PREFACE

Two years ago when revising my book on "Infection, Immunity and Specific Therapy" for a third edition, I found it necessary to rewrite entirely the section on chemotherapy and I resolved at that time, with the kind consent of the publishers, to present the subject, including the general and specific treatment of syphilis, in a separate monograph, owing to the very large amount of clinical and laboratory data requiring inclusion and discussion.

I have considered the chemotherapy and general treatment of syphilis in considerable detail, not only because of the great practical importance of the subject, but because I believe that the greatest advance in this new field of therapeutic science has been made in the treatment of syphilis, that its specific and general treatment best serve as examples of the problems and as guides to present and future lines of clinical and laboratory investigation in the chemotherapy of other diseases, and above all, because there is a real and practical need for a treatise devoted principally to the modern treatment of this widespread disease.

Chemotherapy usually conveys the idea of specific therapy, and properly so, but its practical applications are by no means limited to the treatment of syphilis, malaria and a few other infectious diseases, as popular impressions would indicate. It is true that most advance has been made in the treatment of syphilis, relapsing fever, frambesia tropica and other spirochetic infections; in trypanosomiasis, leishmaniasis, schistosomiasis, piroplasmosis, malaria, amebic and other protozoan and metazoan infestments, but some real progress, with practical applications, has been made also in the great and important field of bacterial diseases and especially when chemotherapy is employed for the treatment of local as well as of systemic infections. In other words, the local disinfection of tissues by chemical agents properly belongs to this new field of therapeutic science and greatly broadens its field of application and usefulness.

It is true, however, that some of the original ideas and theories of chemotherapy begin to show themselves inadequate for our expanding knowledge of the processes concerned and require reconstruction, though without either hasty or wholesale rejection of those principles which served Ehrlich and other early workers so well. But the original idea of chemotherapy, tending to shift the focus of attention from the infected host to the invading parasites by producing chemical agents capable of direct destruction of organisms without the coöperation of the host, has been questioned and especially in relation to the disinfection of the tissues in systemic infections, although this simple mechanism may, and probably does, hold good to a large degree for the disinfection of the tissues by local or topical application of parasiticidal agents.

But if the mechanism of chemical disinfection of the tissues involves, as it may, coöperation on the part of the host, sometimes with the production of really new chemical compounds following administration, so likewise that phase of chemotherapy touching upon the physiological and toxic

effects of chemical compounds and drugs for the body cells has proved to be more complex than originally surmised and in large measure has become reunited with its parent subject of pharmacology, to the distinct advantage of therapeutic science.

Naturally, my laboratory and clinical experience have enabled me to lay particular emphasis upon the biological phases of chemotherapy and I have attempted to strike a proper balance between the purely theoretical and practical phases of the subject. My training and experience have not enabled me to delve deeply into the intricate chemical phases, but even were it otherwise, I should have hesitated doing so because of the present chaotic state of our knowledge of this portion of the subject. While this phase has not been neglected or its primary and fundamental importance underestimated, both my laboratory and clinical experience have enabled me to write especially upon the biological aspects and I have embraced the opportunity for including an account of a large amount of hitherto unpublished laboratory and clinical investigations. Necessarily, in a subject like chemotherapy, theoretical discussions must be included and they serve a very useful purpose, but I have endeavored to lay particular emphasis upon the practical phases and applications of chemotherapy in the treatment of disease, which, after all, is the final aim and purpose of this new division of therapeutic science. Indeed, while theory and systematized laboratory investigations have led to results of major importance in practical therapeutics, and must continue to exert the leading and important rôles in the advancement of chemotherapy, yet a reasonably intelligent empiricism is still required and contributes in no small degree toward material advance.

Chemotherapy is properly commanding a large share of attention and effort in medical research, and I have endeavored to make my volume of service to both the investigator and the practicing physician. The subject necessarily touches upon every specialty in the practice of medicine and surgery, not only because it concerns the treatment of infectious diseases in general, but of syphilis in particular, to which every organ and tissue of the human body is vulnerable. As previously stated, the treatment of syphilis has received special and detailed consideration, and while prevailing opinions and methods on the treatment of this disease are numerous and confusing, I have not hesitated to describe with detail methods for the treatment of the different stages of syphilis based upon my laboratory and clinical observations. Few are in better position than I to realize that routine methods for the treatment of syphilis are neither possible nor desirable, yet it is far better to have methods subject to variation to meet individual conditions than to have no methods at all. Throughout the work, the words "arsphenamin" and "neoarsphenamin" are used as synonyms or substitutes for the words "salvarsan" and "neosalvarsan."

The task, while a labor of love, has been by no means a light one. An enormous literature required perusal, sifting and classification, but I hope that I have succeeded in including a sufficient number of references to the important publications to render this monograph of value for reference purposes. I cannot aspire to have included all the references; some, and doubtless important ones, have escaped attention, but I have made no attempt to cover all the available literature on the treatment of syphilis, because this would have materially altered the essential character of the volume and enlarged it too greatly. Neither can I hope to have escaped making mistakes and failing to detect errors in the reading of proofs, but I shall be grateful for having these brought to my attention for correction.

Since the larger part of our knowledge of chemotherapy has been gained from studies on the lower animals, it is not strange that these were early and directly benefited by the practical application of this knowledge in the treatment of some of the protozoan and metazoan diseases to which the lower animals are subject. I have, therefore, included in this work an account of those practical applications of chemotherapy having a direct bearing upon veterinary medicine.

Many illustrations have been included, and it is hoped that they will serve to elucidate the text and to teach, rather than merely to embellish.

In conclusion, I beg to express deep appreciation of the assistance given by Miss Christine Catrevas in reading the proofs and of the unvarying efficiency and courtesy of the publishers.

PART I

PRINCIPLES OF CHEMOTHERAPY

CHAPTER I

GENERAL PRINCIPLES OF CHEMOTHERAPY

Development of Modern Chemotherapy.—From the earliest times, healers of the sick have sought specific remedies in the form of drugs or methods that would always and unfailingly effect the cure of a certain disease, and this search has been extended for a single remedy that will cure all diseases, regardless of their origin and nature. To this end, throughout the ages experimentation, conscious or otherwise, has gone hand in hand with medicine. Countless substances gathered from the vegetable, animal and mineral kingdoms have been experimented with, but for the most part they have been discarded. Despite this long and persistent search for specifics, until comparatively recent times but three remedies have been found worthy of being regarded as specifics, namely, mercury for syphilis, discovered about 1500, cinchona bark for malaria, discovered by the Indians of Peru and brought to Europe by the Jesuits in the 17th century, and ipecacunha for dysentery, discovered by the natives of Brazil and introduced in Europe at about the same time. In this sense, therefore, chemotherapy is not entirely of recent development.

But modern chemotherapy as a new department in pharmacology and therapeutic science, while doubtless stimulated to some extent by these traditional remedies, has had its origin largely in the work of Ehrlich, who as a medical student was greatly impressed with Heubel's work on lead poisoning. This gave him the basis for the idea "that the ways and means by which drugs are distributed over the body must be of the greatest importance in the rational development of therapeutics." This thought guided him into a valuable series of studies upon the selective affinity of synthetic dyes for blood and other body cells and these in turn quite naturally into a consideration of the selective affinities of chemical agents for parasites which led him to pronounce "*corpora non agunt nisi fixata*" as a basic principle for this new science—that parasites can only be destroyed by those materials for which they have a certain affinity and by which they are fixed or "anchored" by the parasites. This combining affinity of parasites for chemical agents was designated by Ehrlich as *parasitotropy*, but he also knew that they had a combining affinity for the cells of the body designated as *organotropy* and that only those substances can be employed as medicaments in which organotropy and parasitotropy stand in proper proportions.

Doubtless, the discovery of natural and acquired antibodies in diseases and especially the protection and curative activity of diphtheria antitoxin, greatly strengthened Ehrlich's hope and dream of evolving chemical agents capable of reaching and destroying the parasitic causes of disease without injury to the cells of the host. As he stated on one occasion, the antibodies have "no affinity at all for the substances of the body, but they rush exclusively at the parasites. Therefore, in this case organotropy is reduced to zero, parasitotropy is absolute and the antibodies represent magic balls which seek their unerring aim." He never hoped that chemotherapy would ever reach this ideal of specific serum therapy, but that with chemical agents "we shall be obliged to use all our strength to take our aim very accurately in order to hit the parasites as much as possible, the body as little as possible."

But the hopes for serum therapy of various bacterial diseases, aroused by the remarkable success of diphtheria and tetanus antitoxins, did not materialize and when it was realized

that for certain forms of infection, several of which had proved to be infections by protozoa, the body was unable to produce antibodies sufficient for eradicating the disease and that curative immune serums could not be produced, the question arose whether, with the rapidly growing field of synthetic chemistry, man could not match nature's achievements by synthesizing chemical compounds specifically adapted for uniting with and killing the parasites when administered in subtoxic amounts.

Already in 1887 synthetic chemistry had evolved acetanilid (antifebrin) and other substances from coal tar, and while these antipyretics, narcotics and anesthetics were but symptomatic remedies, yet their production opened up a wide field for investigation in chemotherapy. Naturally the synthetic coal tar dyes first attracted the attention of Ehrlich and his colleagues and when Laveran and Mesnil showed how trypanosomiasis could be produced experimentally in mice and rats, the conditions were ripe for therapeutic experimentation in this field, which soon culminated in the discovery by Ehrlich and Shiga of a trypanocidal dye designated as "trypan-red." This was soon followed by the discovery of "trypan-blue" and "Afridol violet" by Mesnil and Nicolle, the latter compound being of special significance because it differed from any previously tested in that its central nucleus was diamino-diphenyl-urea and the forerunner of that valuable colorless, water-soluble salt of a complex sulphonic acid synthesized fifteen years later and known as "Bayer 205" for the treatment of trypanosomiasis.

In the meantime, the parasite of syphilis having been discovered by Schaudinn and the trypanocidal activity of atoxyl, a drug which had been synthesized in the late sixties by an obscure French chemist, Beauchamp, having been discovered by Thomas and Breinl, Ehrlich began his epoch making work with the organic arsenicals, which so impressed him with chemotherapeutic possibilities that he was lead to announce: "*Quod non sanat ferrum, sanat arsenicus; quod non sanat arsenicus, sanat ignis*" (What iron does not cure, arsenic cures; what arsenic does not cure, fire cures) and ending with a complete justification of his faith by the synthesis of salvarsan (arsphenamin), the greatest triumph of modern chemotherapy.

Thus it will be seen that modern chemotherapeutic science is based upon the work and discoveries of many individuals, not only in the realm of synthetic chemistry, but likewise in the fields of parasitology and immunology. No doubt the discovery of the trypanosomes and spirochetes and the means of producing experimental infections on a large and cheap scale was a wonderfully fortunate circumstance, for had the early experiments in chemotherapy been conducted with the bacteria, disappointments would probably have extinguished enthusiasm by a lack of sufficient success and encouragement as subsequent events have amply indicated. To this extent "chance" surely played an important part, just as it did when the discovery of *Spirochæta pallida* induced Wassermann and his colleagues and Detre to try the complement-fixation test in syphilis, in which disease experience has since taught us the phenomenon is more marked and successful than in any other infection.

It is true that some of the theories of Ehrlich are no longer tenable in the light of more recent discoveries and that the underlying principles of chemotherapy are far more complex than he originally conceived them, but yet it is to be remembered that they served him and his colleagues well and proved a wonderful stimulus to chemotherapeutic research, just as his "side chain" theory of immunity stimulated research in the field of immunology. In his opinion, scientific imagination and a healthy optimism were essential for success, and whoever had the opportunity of coming into close contact with him at the time when he worked in small and modest laboratories with few assistants was impressed by the fact that his main activity lay in the mental penetration of problems, as the lack of means permitted him to employ only the simplest technic. But he soon realized that chemotherapeutic discoveries would require a vast amount of work and ample resources. His accomplishments in the field of chemotherapy, which in a certain degree always will be "the sport of experimentation and of chance," were not entirely due to accidental success, but largely the outcome of prolonged, laborious and well systematized laboratory experiments, constituting

the "powder and dynamite" of scientific research and the labors of which can be only fully appreciated by those engaged in similar work.

Definition and Purposes of Chemotherapy.—The term chemotherapy is difficult to define in a brief and concise manner. Of course, chemical agents have been used in the treatment of disease for ages, and following the discoveries of Pasteur, Koch and others of pathogenic bacteria, germicides and antiseptics, attempts were made to disinfect the tissues with mercurial and other compounds, the work of Lister in disinfecting the tissues locally with phenol and related substances meeting with brilliant success. In a general sense, therefore, chemotherapy is the treatment of parasitic diseases with any chemical agent and is almost as old as the art of medicine.

But this definition is not sufficient, because it does not fulfill the principles of the modern definition of chemotherapy, as the term was coined by Ehrlich. It is one thing to *treat* an infectious disease with a chemical agent, but a different one to cure it by destroying the organisms by such means. We may treat a bacterial infection like typhoid fever with small and harmless doses of mercuric chlorid, but we do not cure the disease by such means, because we cannot give sufficient to destroy the bacilli while sparing the tissues and organs of the patient serious damage, which real chemotherapy, the chemotherapy of Ehrlich, seeks to accomplish. Chemotherapy, in a general sense, is simply the treatment of parasitic diseases with chemical agents; chemotherapy, in a modern sense, is the treatment of parasitic diseases by more or less specific disinfection of the tissues by chemical agents without marked or serious toxic effects. The medicament need not be necessarily specific for any one parasite, that is, it need not be strictly mono-parasitotropic; arsphenamin, for example, is destructive not only for *Sp. pallida*, but also for *Sp. pertenuis*, *Sp. obermeieri*, *Sp. gallinarum* and various pathogenic trypanosomes like *Tr. equiperdum*, *Tr. equinum*, etc. Neither need the medicament owe its curative success to a direct parasiticidal activity; it may, for example, accomplish the same end by an indirect means through the production of leukocytosis, stimulating phagocytosis or other immunological defenses. Furthermore, the definition may likewise include the prevention of disease by the destruction of parasites by chemical agents. For example, the prevention of infection in a wound by irrigation with Dakin's solution or some other solution of a chemical substance is, in my opinion, a true example of modern chemotherapy, since it may accomplish the destruction of bacteria without injury to the host.

Chemotherapy may be defined, therefore, as the prevention or treatment of disease by chemical disinfection or inhibition of the parasitic causes without marked or serious toxic effects. The cause may be a bacterial, protozoan or metazoan parasite; prevention or treatment may be the result of a complete destruction of the parasites or a sufficient crippling of their proliferative mechanism (genesistasis) to permit the body cells and fluids to dispose of them. Under ideal conditions the medicament must not harm the body cells or produce toxic reactions at all, but since this ideal is very difficult of actual attainment in the treatment of disease, the requirements may be made less stringent and to read that these effects shall not be of a marked or serious character. The chemical agent need not be necessarily an artificial one produced by synthesis; it may be a natural medicament like quinin of cinchona bark or emetin of epicacuanha. The science of chemotherapy, as defined by Ehrlich, "treats of the action and mechanism of the effects of chemical substances upon cells and especially of drugs upon disease producing organisms." The subject includes, therefore, a study of both organotropic and parasitotropic actions of chemical agents and drugs.

In plain language, the science of chemotherapy constitutes a search for specifics in the treatment of all diseases caused by parasites. The parasites may be so small as to fall into the class of the filterable viruses or as large as the beef tape worm (*Tænia saginata*). They may be on the skin or a mucous membrane and vulnerable to destruction by the direct application or administration of the medicinal agent, or they may be in blood and lymph or entrenched within cells in the depths of an internal organ and approachable only by the enteral or parenteral administration of the medicament. The one essential is that the parasites shall be killed or so crippled that the natural body defenses can complete this task, by doses or amounts of the chemical agent as shall not injure the body cells at all or but to a slight and never serious or fatal extent. When chemotherapy is looked upon in this manner, but yet in the strict modern sense of the term, it is a broad subject intimately concerned with the destruction of parasites by chemical agents and drugs ranging all the way from disinfection of the skin before operation and the destruction of hookworms in the duodenum by carbon tetrachlorid to the routing out of *Sp. pallida* in the aorta of a syphilitic by arsphenamin or one of its congeners.

Parasitotropism and Organotropism in Relation to Chemotherapy.—It will be observed, therefore, that a special and selective affinity or combining power of the chemical agent or drug for the parasite is the predominant thought in modern chemotherapy. As previously stated, Ehrlich designated this state as *parasitotropy* or *parasitotropism* and it is pertinent to inquire into our knowledge concerning the nature and mechanism of this phenomenon. Parasitotropism may be selective affinity of a chemical agent for the protoplasm of a single and particular species of parasite, designated as *mono-parasitotropism* or the affinity may be for several species, designated as *poly-parasitotropism.* Up to the present time, a strictly mono-parasitotropic substance is unknown; at least, I do not know of any chemical agent or drug that is not capable of destroying more than one species of parasite, although its effects may be limited to parasites closely related biologically. Arsphenamin and its congeners, for example, possess a parasitotropism not only for *Sp. pallida,* but also for *Sp. pertenuis*, *Sp. recurrentis* and even for various trypanosomes; quinin is well known as a general protoplasmic poison and the dyes possess a parasitotropism for many different bacteria, etc.

Parasitotropism is not necessarily synonymous with parasiticidal activity. In other words, it is possible for a chemical compound to possess an affinity for the protoplasm of a parasite and to enter into combination with it without necessarily killing the parasite, as, for example, in the case of some of the dyes; indeed, the very reverse may occur and the virulence and activities of the parasites undergo a temporary increase, as in the production of Jarisch-Herxheimer reactions in syphilis by the administration of mercury or arsphenamin and the increased numbers and activity of trypanosomes in the blood of patients with African "sleeping sickness" following the administration of "Bayer 205." However, the parasitotropic activity of a chemical compound usually bears an important and primary relationship to parasiticidal and curative activity, although a compound may still prove therapeutically effective without necessarily involving the questions of parasitotropism and parasiticidal activity or inhibition.

Organotropism on the other hand, refers to the selective affinity of chemical compounds and drugs for the blood, lymph and fixed tissues of the body. Naturally, it bears a very important relation to the pharmacological action of drugs and to toxicology. Instances of selective activity of drugs like strychinin, digitalis, morphin, etc., are so numerous and well

known, that it is not necessary to discuss them here in relation to chemotherapy. It may be stated, however, that the selective effect of drugs upon body cells does not necessarily require that they shall enter into chemical union with the protoplasm of the involved cells, but the general principle holds good that the mechanism and nature of parasitotropism and organotropism are very probably identical. When further information is gained, we shall probably learn that the mechanism of both is exceedingly complex, although fundamentally the same, and involving the questions of chemical or physicochemical interactions between parasite and body cells and the chemical agent or drug.

Chemotherapeutic Index.—In order to express the important relation between organotropism and parasitotropism, Ehrlich coined the phrase *chemotherapeutic index* for expressing the relation between toxicity of a compound for the body (organotropism) and toxicity for the parasites (parasitotropism). The ideal and aim of chemotherapy is to evolve compounds with a minimum of organotropism and a maximum of parasitropism or disinfectant activity. As I shall discuss in the succeeding chapter, toxicity or organotropic tests are commonly conducted by administering compounds to the lower animals according to body weight and expressing the results in terms of the smallest amounts causing immediate death or death in twenty-four hours (*dosis lethalis*) or according to the largest amounts per body weight borne with or without symptoms and histological changes for an arbitrary period, like ten days, and designated as the *maximal tolerated dose.*

The parasitropic, curative or disinfectant effects of the compound are then determined by administering it to animals infected with the chosen parasite and the results expressed in terms of the smallest amounts per kilogram of body weight capable of sterilizing completely the blood and fixed tissues. This may be designated as the minimal curative dose (*dosis curativa*) and the whole expressed in the form of an equation as follows:

$$\frac{\text{Maximal Tolerated Dose per Kilogram}}{\text{Minimal Curative Dose per Kilogram}} = \text{Chemotherapeutic Index}$$

A concrete example may better explain this subject. Arsphenamin (disodium salt) by intravenous injection is generally borne by white rats in dose of 0.120 gm. per kilogram for an indefinite period, while 0.140 gm. may prove fatal in a few days; the former, therefore, is approximately the maximal tolerated dose. When administered to rats infected with *Tr. equiperdum*, the smallest dose per kilogram capable of completely eradicating the infection may be 0.004 gm., the minimal curative dose. The results, therefore, are expressed as follows:

$$\frac{0.120}{0.004} = 30 \text{ (Chemotherapeutic Index)}$$

This means that the single minimal curative dose was 30 times less than the single maximum tolerated dose. Various minor modifications of this method have been described by different authors, but the foregoing illustrates the basic principles underlying the determination of the chemotherapeutic index.

The chemotherapeutic index of a compound is subject, however, to wide variations and fluctuations according to the test animal and particular strain of organism employed. In the first place, the toxicity of a compound varies in animals of different species, the mouse, for example, being able to tolerate

larger doses of most compounds than the rat, and the rat more than the dog. Off hand, it would be supposed that a strain of trypanosomes, say *Tr. equiperdum*, would be equally susceptible to a drug like arsphenamin in any susceptible animal, but I suspect that this is not the case and in my experience the organisms floating in the blood of the mouse are sometimes more vulnerable to compounds than those in the blood of the rat and in either animal they are more vulnerable than in the blood or tissues of the guinea-pig and rabbit. Why this should be so has not been adequately explained, but in a general manner the chemotherapeutic index of a compound for pathogenic trypanosomes is apt to be higher in the mouse than in the rat and higher in both of these than in the guinea-pig or rabbit.

Furthermore, the chemotherapeutic index varies among different strains of the same organism. For example, it is lower against *Tr. brucei* than against *Tr. equiperdum*, which may be due to the greater virulence of the former and consequently the larger doses required for the protection and cure of the inoculated animal. But this is not the whole story, since *Tr. lewisi*, but feebly virulent at best, is usually more difficult to kill than the virulent trypanosomes and consequently is apt to give the poorest chemotherapeutic index of all.

There is, therefore, a curious and intimate relationship between toxicity for the host and toxicity for the parasite as expressed in the chemotherapeutic index. In all probability, the metabolization of the compound following administration influences both properties. But for some reason a compound may be less toxic for one animal than for another; likewise less toxic for one strain of a parasite than for another strain of the same species. In a general manner, if a compound has slight avidity for the cells of the host, apparently more is left over, as it were, for the destruction of parasites and yielding thereby a high chemotherapeutic index. If the chemical agent has a strong avidity for the parasites and many parasites are present, the body cells may be spared accordingly, suggesting that the greater tolerance of syphilitics for the arsenicals and mercurials than non-syphilitic individuals may be due to some such mechanism and relationship.

Parasitotropism in Relation to Leads in Chemotherapy.—Parasitotropism is of fundamental importance in relation to "leads" or the discovery of "optimum centers" (Ehrlich) in chemotherapeutic investigations. By this is meant the discovery of a particular kind or group of compounds possessing a selectively high disinfecting effect for a certain parasite *in vitro* and *in vivo*, which by further modifications of the molecule may have its parasitotropism and organotropism so brought into a workable range that the compound may be safely used in the practical treatment of disease. This is the very life and soul of chemotherapeutic research, but unfortunately we know so little of the fundamental laws and principles of parasitotropism that the search for "leads" is almost purely one of guess work and actual experiment. In other words, most leads are furnished by empiric clinical experience indicating that a certain class of compounds appears to influence an infection in a particularly selective manner or by actually carrying out an extensive and laborious series of tests with a certain organism and different compounds to determine which, if any, displays a sufficiently high selective parasitotropism to warrant adopting it as a compound or group worthy of special development. As stated by Ehrlich in his Harben lectures, "it must be the goal of our experiments to search, by systematic chemical studies, for the most suitable substances, and thus to discover the 'optimum centers.' This problem is by no means an easy one, since according to my experience of many years, which agrees entirely with that of Mesnil, different animal

species have different optima, and therefore the work must be specially done for each species of animals and each kind of trypanosomes."

As will be discussed shortly, I believe parasitotropism is purely a matter of chemistry and until we know more about the chemistry of the protoplasm of parasites and of chemical constitution of our compounds in relation thereto, we shall be working largely in the dark groping for leads on the basis of actual trial and experiment instead of on the basis of concrete knowledge of the underlying principles and laws. There is a great need, therefore, for more research upon the fundamental principles of chemotherapy and especially upon this subject of chemical constitution of both parasites and compounds in relation to parasitotropism and leads.

Parasitotropism and Organotropism in Relation to Carriers of Parasiticidal Agents and Vital Staining.—Of further interest and importance in relation to this subject of the specific parasitotropism and organotropism of chemical agents in therapeutic science, is the possibility of employing substances not of themselves parasitocidal but possessing a high degree of parasitotropism, as carriers or vehicles for transporting parasiticidal agents to organisms in the tissues. As von Wassermann said of eosin-selenium mixtures in the treatment of experimental cancers, the dye may act as a "railroad" for conveying the selenium to the cells, although it is not of itself cytotoxic. This idea has long held sway in chemotherapeutic research and especially in relation to the dyes, which may not be parasiticidal of themselves but yet, possibly, capable of sneaking a destroyer into the protoplasm of parasites by utilizing a dye possessing a high degree of parasitropism with low organotropism and attaching to it a more active parasiticidal agent. For local use, however, the dye need not necessarily possess a selective parasitotropism; it may only be capable like fluorescein, of staining organisms and other cells in a nonselective manner, but yet serve as a useful carrier of a potent parasiticidal agent, as the mercury of mercurochrome.

While the dyes may serve a very useful purpose in this regard for aiding the deeper penetration of parasiticidal agents when directly applied to the skin and mucous membranes, they have not so far been successfully utilized for the chemotherapy of systemic infections by the internal or intravenous administration of compounds. This subject involves the question of vital staining which is far more complicated and perplexing than the mere staining of cells by local application and involves more intimately the subject of selective parasitotropism. It is, however, a matter of great importance and especially in relation to the chemotherapy of tuberculosis and other bacterial infections where a great stumbling block to success appears to be a lack of penetration of chemical disinfectants for localized tissue infections even though the disinfectant is present in the blood in parasiticidal concentrations. Indeed, Ehrlich began his work in chemotherapy from the standpoint of the behavior of dyes in the body, so-called *vital staining*, and with Herter expressed the opinion that "it will always be of great interest to produce dyes in which a strongly acting residue is contained, as possibly, in a part of these derivatives, a toxic effect may be produced with the possibility of studying the connection between distribution and effect by means of biological and microscopical investigations." In Ehrlich's own words, chemotherapy in the beginning was essentially a matter of dye therapy, since the quality of a substance to penetrate, locate and become fixed in certain cells and tissues would appear to be of fundamental importance; in his own work he classified the dyes as neutotropic, lipotropic or polytropic, according to their fixation mainly by the nervous system, the fats or the tissues in general of the body.

Needless to state, a large amount of investigation has been devoted to the mechanism of vital staining, but unfortunately our knowledge is still very imperfect although it may be stated that the phenomenon is largely one of colloidal chemistry in which the physico-chemical state of the solutions is of fundamental importance; for example, true solutions apparently do not stain vitally, whereas the so-called hydrophilic colloids possess this property in greatest degree.

Trypan-red and trypan-blue are readily soluble in water and when injected into the lower animals are taken up by special connective tissue cells called by Goldmann[1] "pyrrhol cells," which are so numerous and so filled with deeply colored granules that the connective tissue of the body appears deeply stained. Lewis[2] found that trypan-red penterates to the center of fully formed tubercles in rabbits and DeWitt[3] observed that both dyes penetrated into even the necrotic centers of large tubercles in the spleen and liver of guinea-pigs within a few hours after injection, but unfortunately the tubercle bacilli themselves were stained poorly or not at all. Furthermore, as I shall discuss with more detail in Chapter V, these and other dyes are almost totally lacking in bactericidal properties for tubercle bacilli both *in vitro* and *in vivo*, but since they penetrate tubercles so well it was thought that they may act as vehicles for carrying more potent substances in the form of combination compounds of silver, gold, copper, mercury, iodin, phenol, etc., discussed at length in Chapter III. Suffice it to state at this time, only a few of the mercury compounds have appeared to influence the disease in guinea-pigs, as indicated by a somewhat longer life with less involvement of the tissues.

It would appear, therefore, that dyes capable of merely staining the tissues of an infected area are insufficient for serving as vehicles for bactericidal substances; to be useful in this connection they should possess a selective staining and parasitotropism for the organisms themselves in these tissues and it is possible that combinations with gentian-violet, fuchsin and other dyes may be ultimately produced for the chemotherapy of staphylococcus, streptococcus and other infections. However, if combinations of this sort were found capable of laying down bactericidal substances only in the tissues of a tubercle or other inflammatory exudate, it is reasonable to hope that such may raise the bactericidal properties of the lymph and cells to therapeutic concentrations capable at least of restraining a further extension of the infection.

Sternberg[4] has suggested combining bactericidal substances with tuberculin for the purpose of employing the latter as a vehicle for the selective transmission of bactericidal substances to tubercles, but in all probability such compounds would likewise fail in the sense of failing to convey the disinfectant to the bacilli themselves. It may be, however, that the production of mild focal tuberculin reactions in combination with chemotherapy and especially the intravenous administration of gold and mercury compounds may be of aid by reason of the hyperemia and serous exudation facilitating the penetration of tubercles with bactericidal agents. Furthermore, this whole question of selective parasitropism of dyes and other compounds is influenced by the question of their solubility reactions and other physico-chemical properties, which I shall discuss shortly in relation to the matter of penetrability of tissues and organisms by chemotherapeutic agents.

Theory of Chemoreceptors in Relation to Parasitotropism and Organotropism.—Naturally, the mechanism of parasitotropism and organotropism is of fundamental importance in chemotherapy and it is just here that our ignorance of this subject hinders and delays progress in therapeutic science

and places the subject so largely at the mercy of "chance" in its development. There is a greater need, therefore, for more investigation along these fundamental lines with the hope that accumulated data and experience will gradually establish the nature and mechanism of the selective affinity of chemical agents for parasites (parasitotropism) and for the body cells (organotropism) and the relation between these properties and the chemical constitution of the compounds.

In searching for a working theory and hypothesis, it was but natural for Ehrlich to swing his view of nutri-receptors and the side-chain theory of immunity into the arena of chemotherapy with the result that a similar theory of receptors was advanced in explanation of parasitotropism and organotropism. As stated in his Harben lectures: "I also wish to lay special stress upon my view that the drugs are attracted by and bound to the protoplasm molecule by certain atom groupings. I am inclined to look upon this as somewhat analogous to the binding of the toxins and of similar protein bodies. Yet on the other hand, there are fundamental differences between the two. For, as I have always insisted, the mode of binding the toxins is peculiar in so far as it is the result of a certain kind of assimilation which obviously consists in processes of a more or less synthetic nature. These toxin-receptors which produce immunity are bodies of a more independent character, and appear to be especially destined for purposes of assimilation. This high degree of independence is evidenced by the fact that, in conformity with my side-chain theory, these receptors are very easily reproduced by the cell in excessive numbers, and after being separated from the cell, find their way into the blood.

"I have now formed the opinion that in like manner a part of the chemically defined substances is attached to the cell by groups corresponding to these receptors; these atom groupings I will distinguish from the toxin receptors by the name of '*chemo-receptors*.' This view is more particularly supported by the fact that an atoxyl-fast strain of trypanosomes is also resistant to a number of substances related to atoxyl, but otherwise showing widely different chemical characteristics. Evidently, therefore, the arsenic acid radical here represents the point of attack which is common to this series of substances. It is the arsenical radical as such, which is bound by the chemo-receptors. These chemo-receptors must, however, be regarded as of a simpler structure than the toxin-receptors. They do not show a similar degree of independence; they cannot therefore, become increased in chronic intoxications, and since they are sessile, they cannot be thrown off into the blood. The number of such chemo-receptors for poisons which a trypanosome cell possesses, represents the number of points of attack. By means of the resistant strains we can count off, one by one, these groups that are open to attack."

According to this theory, therefore, the matter of whether or not a chemical agent displays selective affinity for parasites or body tissues is determined by the presence or absence in these cells of special receptors for the compounds, that is, upon the matter of distribution of specific chemoreceptors, in exactly the same manner that the nutrition of the cells depends upon the presence of receptors for nutriment (nutri-receptors) and that the action of bacterial and other toxins for cells depends upon the presence of special receptors for their anchoring, before they may enter into relationship with the protoplasm. Ehrlich suggested, as quoted above, that these *chemoreceptors* may probably possess a less complex structure, similar to the receptors of the first order of his side-chain theory for simple toxins, that they are more firmly attached to the cell, and that, accordingly, they are less readily cast off, thus explaining why crystalline chemical substances are, as a general rule, incapable of eliciting the production of antibodies. This theory was based upon the discovery that trypanosomes and spirochetes may develop a state of "resistance" or "fastness" to a chemical agent or drug, which Ehrlich thought may be due to a modification of these receptors and which I shall discuss shortly with more detail. Ehrlich also sought to explain the effects of "combination therapy" on the same basis, that is, the possibility of attacking parasites by a combination of chemical agents for which the organisms possess suitable chemoreceptors to effect the union, believing that in this manner the maximum of parasiticidal effect is to be gained with the minimum of injury to the host.

According to this theory, chemical agents and drugs cannot act upon either parasites or body cells unless they are first fixed by suitable chemoreceptors (*corpora non agunt nisi fixata*). Therefore, when arsenic is administered, it is "fixed" by the arseno-receptors of certain cells; mercury in turn is "fixed" by other receptors and so on through an interminable list. Ehrlich thought that the basic principle of chemotherapy was the possibility of producing chemical substances carrying side-arms capable of being fixed by the receptors of parasites to a much greater extent than by the body cells. Presumably it is not necessary that the whole molecule of a chemical agent possess a combining affinity for certain receptors; if one or more atom groups become attached, it is presumed that it carries with it the remainder of the molecule. Moreover, that atom group that is anchored or is responsible for the anchorage of the entire molecule, need not possess any of the properties of the entire molecule or of any part thereof.

Needless to state any theory advanced by the father of modern chemotherapy is deserving of the closest analysis and this theory has at least the merit of having stimulated considerable work on the nature of "drug fastness." But just as his side-chain theory of immunity has been accepted too readily and in the spirit of established fact to the detriment of immunological research on the fundamental principles of immunity, so the theory of chemoreceptors must be remembered as only a theory without permitting it to discourage efforts towards placing parasitropism and organotropism on a purely chemical or physico-chemical basis subject to natural laws. This involves the chemistry of both the body cells and parasites on the one hand, with the chemical constitution of the disinfectant on the other, and it may be now profitable to enquire more closely into these subjects in relation to the nature and mechanism of parasitotropism and organotropism.

Chemical Constitution of Compounds in Relation to Parasitotropism and Organotropism.—Undoubtedly alterations in the chemical constitution of compounds may profoundly influence their toxicity for both host and parasites, but in spite of a great deal of investigation in this field with different classes of compounds and especially those of arsenic, mercury and the dyes, it is still impossible to formulate laws or to synthesize new compounds, the parasitotropism and organotropism of which may be predicted with certainty by their chemical constitution. For this reason, biological experimentation, that is, toxicity and parasiticidal tests, continues to be an integral and important phase of chemotherapeutic investigation and, indeed, owing to the sharp limitations of these procedures, chemotherapy is still largely on an empiric basis.

In succeeding chapters upon the dyes, arsenical, mercurial, hexamethylamin and other compounds, I shall pass in review data bearing upon the relation of chemical constitution to organotropism and parasitotropism; naturally most information has been gained with the arsenicals, but the mass of data is too voluminous to permit of a detailed discussion in this place. Unfortunately, many investigators, probably the majority, have not systematized their work or stuck long enough to any one group of compounds to permit them to study these fundamental relations, a feverish desire to evolve remedies of striking properties quite generally preventing the less spectacular, but nevertheless highly desirable, systematic studies devoted to a painstaking and persistent study of chemical constitution in relation to toxicity and parasiticidal activity and employing the simplest biological methods in order to render all tests strictly comparative with the minimum of experimental error, which will permit the influence of minor alterations in chemical constitution to be properly evaluated.

Even when systematic studies have indicated that the substitution of this or that molecular group renders the compound more or less toxic or parasiticidal, the mechanism of the alteration is not generally elicited, because both of these properties are subject to profound changes by various physical

and physico-chemical agencies aside from the mere matter of direct chemical combination of the compound with the protoplasm of either parasites or body cells. The very magnitude of the subject, the numerous factors to be kept in mind and subjected to study, the frequency of paradoxical and totally unexpected results, contribute toward rendering disinfection in relation to chemical constitution one of the most perplexing of studies, demanding on the part of the investigator an unusual degree of tenacity and the courage to work for years in the face of disappointments. But, as long as the work is arranged on a systematic and orderly basis with accurate and acceptable methods, it cannot fail to be of value, even though it does not result in the production of a remedy of practical application.

In work of this kind the important point is to chose a class of compounds of promise for the treatment of a certain infection, just as Ehrlich concentrated upon the organic arsenicals in relation to the treatment of experimental spirilloses and trypanosomiases. When it was found advisable to reduce the toxicity of arsphenamin, systematic investigations indicated that the introduction of the formaldehyd residue reduced toxicity, just as the introduction of an acetyl (CH_3CO) residue reduced the toxicity of phenetidin and other anilin derivatives. In neoarsphenamin, for example, a condensation product of arsphenamin with sodium formaldehyd sulphoxylate, with complete substitution of one amino-group and partial substitution of the second, both toxicity for the host and for spirochetes is reduced, but the former in greater ratio than the latter; in sulpharsphenamin, both amino-groups are apparently closed with a further reduction in toxicity and especially of pain and irritation upon subcutaneous injection. In the way of additional examples of the influence of molecular substitutions in the organic arsenicals, I may briefly allude to the results observed by Fourneau and his colleagues[5] in their extensive studies with the phenylarsenic acids. The animo-group placed in the para- or meta-position always increased slightly both spirocheticidal and trypanocidal activities with a reduction in toxicity, but these effects were not observed when the animo-group was placed in the ortho-position. The placing of a second amino-group near the amino-group in the para-position still further reduced toxicity, while a third amino-group increased toxicity and diminished therapeutic activity. The introduction of the phenol group OH increased the parasiticidal activity of phenyl arsenic acid to an even greater extent than the substitution of an amino-group, but the position of the OH group was found to be less important. In compound "189" of their series, blocking of the amino-group always reduced trypanocidal activity, no matter what was the nature of the acid rest. Acetylation of the amino-group of this compound, however, reduced spirocheticidal properties but slightly, as shown by the effects observed with compound "190" or "stovarsol." Blocking of the amino-functions of atoxyl gave variable results according to the acid rest: a formic acid rest, for example, increased toxicity and especially for the nervous system while an amino-benzoic rest diminished these effects, etc. It was on the basis of such studies that Fourneau formulated his opinion that the so-called neurotropism of pentavalent arsenicals observed by Ehrlich and others, were due to the presence of impurities, a subject which I will discuss with more detail in Chapter XLVI.

As so clearly shown by Ehrlich and his associates, the valence of the organic arsenicals, therefore, bears a very important relationship to both toxicity for the host and parasiticidal activity, valence being the energy capacity of an element expressed in numerical terms, hydrogen being selected as a basis for its measurement and taken as the unit, namely, 1. When an atom of an element requires only one hydrogen to form a chemical compound, the element is considered univalent. Elements with greater energy capacity are bivalent, trivalent, etc; moreover, they may exist in two or more conditions. For example, iron is both bivalent and trivalent; mercury, univalent and bivalent.

Arsenic belongs to the group of pentavalent elements. In pentavalent condition, all its energy is bound, the capacity for further reaction being greatly diminished. On the other hand, in trivalent condition it is unsaturated, the potential reactivity being much greater.

The chemotherapeutic investigations carried out by Ehrlich and his associates have developed the fact that arsenic in the trivalent condition is a more powerful trypanocide and spirocheticide than arsenic in the penta-

valent condition. There would, in this connection, appear to be established a relationship between the energy capacity of the compound and its destructive influence on the parasites in question. This important observation and, moreover, the fact that chemical elements must be linked to the nuclear carbon in order to exert their fullest effect on the pathogenic microörganisms, are the two most important advancements in modern chemotherapy. This, however, is probably not the whole story, if Voegtlin and his associates[6] are correct in their claim that the difference in toxicity and trypanocidal activity of pentavalent and trivalent arsenic is due to the fact that the pentavalent forms must be reduced to trivalent oxids and that the elimination of pentavalent arsenic is ordinarily so rapid that only a small proportion can be changed into these more toxic substances.

As previously stated, a complete discussion of these interesting and highly important questions would lead me too far afield at present, because each group of compounds introduces special features more or less peculiar to its class. With compounds of mercury, silver and similar heavy metals, for example, I believe that the matter of ionic dissociation bears the most important relation to both toxicity for the host and toxicity for the parasites. Furthermore, the chemical constitution of the protoplasm of body cells and parasites may influence in varying degree the question of chemical or physicochemical interaction between a chemical compound or drug with cells, a subject which deservedly commands a great deal of interest.

While drugs of similar chemical constitution may possess similar biological properties, yet definite changes in the molecule often produce profound alterations in toxicity for body cells and parasites. Certainly the action of chemical compounds is not determined so much by the elementary composition of the substance, as by the manner in which the elements are combined; although with the compounds of heavy metals like mercury, bismuth, gold, copper, tin, etc., I believe that biologic actions are largely influenced by the degree and rapidity of ionic dissociation and that chemical constitution influences toxicity for both host and parasites largely by the looseness or tightness, as it were, of the elementary metal in the compound.

Changes in chemical constitution may result in changes in toxicity of a drug for both host and parasites by influencing either chemical combination with these cells or by altering the physical properties and actions of the drugs. Minor changes may not materially alter these biological properties, although these are sometimes sufficient for evading patent rights and trade marks and resulting in the needless multiplication of drugs for commercial purposes. But attempts to construct a general theory of biological action in relation to chemical constitution have so far failed, although a good deal of useful information has been gained in relation to the dyes, arsenicals, cinchonics, mercurials, etc., which I will review and discuss in later chapters devoted to these and other compounds of chemotherapeutic interest.

Chemistry of Parasites and Body Cells in Relation to Parasitotropism and Organotropism.—Unfortunately, there is but very little data available bearing upon what I believe is an important subject in chemotherapy, namely, the affinity of chemical compounds for the protoplasm of parasites and body cells as influenced by the chemical constitution of the latter. Ehrlich has always insisted that the colloidal nature of protoplasm was no argument against the acceptance of his theory of chemoreceptors, since colloids possess certain groupings of atoms which render them capable of reactions of a synthetic nature; but the question of a chemical combination of arsenic with a protoplasmic constituent as influencing organotropism and parasitotropism did not seriously engage his attention, although Meyer and

Gottlieb had suggested that arsenic causes its toxic effect by reacting with a substance which is present in protoplasm in very small amounts. In this connection, the recent work of Voegtlin, Dyer and Leonard[7] upon the union of arsenic with the sulphydryl (SH) compounds of body cells and trypanosomes is highly suggestive and an important attempt to interpret the action of the arsenicals in terms of known biochemical facts. I will describe this work with more detail in Chapter XII, but here it may be stated that, since Heffter[8] demonstrated that the tissues contain a sulphydryl compound held responsible for its reducing properties and since Hopkins[9] succeeded in isolating from yeast and mammalian tissues one such compound, reduced glutathione, of importance in relation to hydrolytic oxidation-reduction processes of the cell, Voegtlin and his associates have brought forward experimental data suggesting that the trivalent oxids of arsenic, with "arsenoxid" as the type, are specific poisons for the SH group of glutathione and possibly other SH compounds in protoplasm with a consequent suppression of vital functions which may explain the toxic and therapeutic effects of the organic arsenicals like arsphenamin and its congeners.

Since both parasites and body cells contain SH compounds, it is necessary to explain the difference in susceptibility of different types of cells to arsenic; as stated by Voegtlin and his associates:

"It might be reasonably assumed that trypanosomes are more easily killed than rats, for the reason that the former contain and are dependent on a smaller absolute amount of SH compounds than the vital organs of the higher animals. Exposure to a certain concentration of arsenoxid would therefore kill trypanosomes, whereas the infected animal would survive. There are other factors which very likely also enter into this problem, such as differences in the permeability for arsenic of trypanosomes on the one hand and tissue cells on the other.

"A similar reasoning might also be applied to the unsolved problem of the specificity of the chemotherapeutic action of arsenicals for certain organisms. It is probable that the only infectious diseases that can be benefited by arsenic therapy are those whose causative agents are dependent on a considerable amount of SH compounds for their normal metabolism. If glutathione really plays such an important part in the life of the cell, then it is not at all surprising that substances such as arsenoxid, which react with the SH group of glutathione, should exert a toxic action, and that the latter should be counteracted by supplying the cell with an extra amount of glutathione. In the final analysis, arsenic would have to be considered as a poison which causes death of the cell by interfering with the oxidative processes governed by glutathione."

So stated the suggestion leaves many aspects of the problem unsolved, but it is a step in the right direction in chemotherapeutic investigation and indicates the advisability and necessity for a more thorough study of the chemistry of both body cells and parasites as a means for solving the mystery of the specific tropism of chemical compounds and drugs on the basis of chemical interactions rather than upon the theory of chemoreceptors. Whether or not the specific parasiticidal effects of mercury and bismuth for *Sp. pallida*, or quinin for the malarial organisms, of emetin for endameba, etc., are explainable upon the same basis, remains to be determined; but it is to be hoped that investigations along these fundamental lines will be undertaken in spite of the numerous and great difficuties to be met and overcome in researches of this kind.

Drug Fastness and Tolerance.—The subjects of drug fastness and drug tolerance may now properly engage our attention since the mechanism involved apparently concerns the matters under discussion in an intimate manner. When parasites possess naturally or acquire an increased resistance to the destructive effects of a chemical agent or drug, the state is designated as *drug fastness* or *drug resistance;* when the body cells acquire an increased resistance to the toxic and pharmacologic effects of drugs, the state is desig-

nated as *drug tolerance*. As a general rule, acquired drug fastness of parasites has commanded most attention, but I believe that acquired drug tolerance of body cells involves the same mechanism and is equally worthy of out attention. Both subjects, and especially acquired drug fastness of parasites, have complicated the practical applications of chemotherapy and greatly stimulated Ehrlich in his synthesis of chemical compounds capable of disinfecting the tissues in one dose, *therapie magna sterilisans*, in order to avoid the possibility of parasites acquiring resistance to the compounds.

Acquired drug tolerance has been known for centuries, that is, that the body may gradually acquire increased tolerance for the effects of a drug when given over long periods of time, as, for example, in the case of opium, morphin and cocain addicts, arsenic eaters, etc., but that parasites were capable of undergoing a similar change was not seriously considered as a possibility and practical therapeutic problem until it was discovered that they may acquire resistance to antibodies (serum fastness) and that trypanosomes may acquire fastness to various arsenical and dye compounds.

Natural drug fastness of parasites analogous to the strain of *Tr. equinum* resistant to the arsenicals described by Halberstaedter,[10] is apparently quite uncommon, but acquired fastness is readily produced experimentally and especially with trypanosomes. An extensive literature has accumulated upon this subject as I shall review in succeeding chapters; here it may be stated that not only various trypanosomes, but also various spirochetes and even bacteria, have been rendered drug resistant by exposing the organisms to increasing amounts of the compound either *in vivo* or *in vitro*. Trypanosomes have been rendered resistant not only to such arsenicals like atoxyl, arsacetin, arsenophenylglycin and arsphenamin, but also to fuchsin, azo dyes, trypan-red and trypan-blue. As a general rule, resistance has been conferred by inoculating mice or rats with trypanosomes and treating them with substerilizing doses of the compound; the surviving parasites ("recidives") are then transmitted to fresh animals followed by the administration of a slightly larger but substerilizing dose of drug and so on until it is ultimately found that the organisms can withstand a dose many times larger than required for the complete destruction of the parent strain. Once acquired this fastness persists for very long periods of time and indeed, indefinitely, as shown by hundreds of passages through mice without loss of this property.

Chemical compounds and drugs vary greatly, however, in their ability to render trypanosomes, and presumably other parasites, resistant to their effects. Even among the arsenicals, considerable variation has been noticed. For example, *Tr. equiperdum* in rats is very easily rendered resistant to arsphenamin, while they acquire resistance to arsenious acid very slowly. In my experience, great caution is required in conducting trypanocidal tests with the arsphenamins, because to inoculate a strain in rats previously injected with arsphenamin or neoarsphenamin, may render the strain highly resistant, this accident having occurred in my laboratory several times during the past ten years. As shown by Browning and Gulbransen,[11] even feeding mice infected with *Tr. brucei* with parafuchsin may render the trypanosomes resistant and indicating that the oral administration of drugs in the treatment of disease may have this undesirable effect. Trypanosomes and spirochetes have also been rendered "fast" to antimonials, mercurials and other compounds, as I shall review in later chapters, but experience has shown that fastness is acquired to the dyes and organic arsenicals, especially the trivalent arsenicals, more rapidly and to a higher degree that is true of most other substances.

Specificity of Drug Fastness.—The drug fastness of trypanosomes and other organisms is not absolutely specific. For example, a strain rendered fuchsin-fast is also resistant to many other triphenylmethane dyes, but susceptible to the arsenicals and other dyes, like trypan-red and trypan-blue. Curiously enough, trypanosomes rendered "fast" to arsenic have sometimes shown fastness to antimony, as reported by Morgenroth and Halberstaedter[12] and others. Another interesting exception to the specificity of drug fastness is the fact that dyes of the orthochinoid type, like arsenic-free pyronin, may induce a resistance to the arsenicals, even though they are totally unrelated to the latter compounds; dyes of the parachinoid type like pararosanilin, on the other hand, do not act in this manner. These exceptions to the specificity of drug fastness among trypanosomes and other parasites bear an analogy to similar conditions in acquired tolerance of human beings to drugs. Thus the chronic alcoholic may display an increased resistance to narcotics like chloroform and ether and the morphin addict is said to be sometimes more tolerant to cocain, etc.

But drug fastness in general exhibits a high degree of specificity and a single strain of trypanosomes may be rendered resistant to several different compounds by treating the organisms in succession with them. Ehrlich has even suggested that a strain of this kind may be of service in chemotherapeutic work by providing, as it were, a "therapeutic sieve;" if, for example, a new substance which kills a normal strain of trypanosomes is tested out against a strain possessing a triple fastness, destruction of the latter organisms indicates that the new compound is unrelated to the compounds employed for rendering the strain resistant.

Another curious fact about drug fastness is that a strain of trypanosomes rendered arsenic fast by carefully adjusted passages through mice may not be fast when inoculated into rats; Ehrlich observed this phenomenon quite early in his work and sought to explain it on the basis that in the rat the chemical compound was less organotropic than in the mouse, leaving, consequently, more of it to act upon the trypanosomes which are still susceptible to the compounds. According to this theory, variations in the organotropism or avidity of a chemical agent for body cells would alter the trypanocidal values, and if the body cells of the rat were less susceptible to a certain agent than those of the mouse, it would yield a higher chemotherapeutic index, provided the trypanocidal activities were the same in each animal. As previously stated, the chemotherapeutic index of a compound may vary with different species of animals for reasons not properly understood, unless it is because of variations in the metabolization of compounds in different kinds of animals, which in turn modify both the organotropic and parasitropic effects.

Nature and Mechanism of Drug Fastness.—With this brief review of some of the observed phenomena of drug fastness of parasites and body cells, we may now inquire into the nature and mechanism of these processes. I prefer to discuss these subjects together because it would appear that the mechanism by which body cells acquire an increased tolerance or fastness to a drug is fundamentally the same as the fastness acquired by trypanosomes, spirochetes, bacteria and other protozoan and metazoan parasites, although it would appear that the trypanosomes may acquire fastness to the trivalent arsenicals and some of the dyes much more rapidly than the body cells. It is not necessary, however, to discuss the question of non-absorption of a drug in relation to these processes which may give the appearance of acquired tolerance or fastness, but variations in elimination may properly engage our attention. It is well known, for example, that trypanosomes do

not acquire fastness to the pentavalent arsenicals as rapidly as they do to the trivalent compounds like arsphenamin. Voegtlin and Thompson[13] have shown that this may be largely a matter of rate of elimination as influenced by the physical properties of the arsenicals, the directly toxic trivalent oxid compounds showing the slowest rate, the pentavalent arsenicals the fastest, and the arsenobenzene compounds occupying an intermediate position. In other words, the compound eliminated most rapidly is apt to be least toxic, least parasiticidal and least likely to induce fastness of both body cells and parasites. Furthermore, the apparent tolerance of some animals to a drug due to anatomical and physiological differences need not engage our attention in the present discussion; for example, the absence of vomiting in rodents receiving emetics or the failure of atropin to quicken the heart of the rabbit because its vagus nerves are not tonically active, etc. But tolerance due to increased destruction of a drug like that of morphin by the serum of rabbits, the remarkable natural tolerance of the hedgehog to morphin, atropin, arsenious acid and bacterial toxins, the matter of individual variations in tolerance among animals and the influence of temperature and diet are more pertinent to the question at hand. Ehrlich and his colleagues sought to explain natural tolerance of both body cells and parasites to a congenital absence of suitable receptors for anchoring the chemical compound, drug or toxin; in other words, that such substances may be present in the blood in high concentration, but yet fail to produce physiological or toxic effects because of being unable to enter the protoplasm of cells. Acquired tolerance was explained on the basis of a modification of chemoreceptors by which their avidity for a certain compound and related substances was reduced although not destroyed, since the tolerance may be broken down by increasing the dose or by transferring the resistant strain of trypanosome to some other animal for which the compound was less organotropic, and thereby leaving more of it for action upon the parasites, as, for instance, an atoxyl resistant strain of *Tr. brucei* from the mouse to the rat. However, in this instance it may be that atoxyl in the mouse forms a combination product with some tissue constituent and particularly the liver, as claimed by Levaditi and called "trypanotoxyl," for which the trypanosomes acquire a specific tolerance or fastness, although just as susceptible to a "trypanotoxyl" formed in the rat as would be a normal strain of the trypanosomes. But I believe that instances of natural and acquired fastness of body cells and parasites, not to be explained on the basis of anatomical and physiological variations in the case of the former, will be ultimately explained on a chemical basis, that is, that natural or congenital tolerance is due either to the absence in the protoplasm of a chemical constituent capable of interaction with the compound or drug administered or the presence of a substance capable of union with it followed by rapid transformation to an inert compound. For example, it may be that the real "chemoreceptor" in cells for the arsenicals are the sulphydril compounds mentioned above and that the increased tolerance or fastness of trypanosomes to arsphenamin and its congeners is due to an increase of these above vital needs capable of uniting with and detoxifying the trivalent arsenical oxid believed to be produced when the arsphenamins are administered. At all events, natural and acquired tolerance or fastness to chemical compounds and drugs are not to be explained on the basis of antibody-production and it would appear likely that the theoretical chemo-receptors of Ehrlich will be ultimately shown to be the presence of chemical protoplasmic constituents for which a chemical compound or drug may or may not have the property of union and interaction with a change into non-toxic substances. In the case of arsenic-fast trypanosomes

even physical changes may become apparent; for example, as shown by Gonder,[14] normal trypanosomes (*Tr. lewisi*) can be stained by certain orthochinoid substances and especially triamonphenazselenonium chlorid, causing the blepharoplast to disappear, while arsenic-fast trypanosomes are stained only after their death. At least, the meritorious work of Voegtlin and his colleagues in relation to the SH compounds in body cells and trypanosomes in relation to the toxicity and fastness of the arsenicals opens up this interesting and important field for pharmacologic investigation in therapeutic science. It is true, however, that many other factors must be considered in relation to the mechanism of drug fastness, toxicity and parasiticidal activity of chemical compounds among which may be mentioned the influence of various physical factors, alterations of surface tension, changes in electrical charge, penetrability, etc., and these may now properly engage our interest in relation to the mechanism of drug action upon the body cells and parasites.

Before leaving this subject however, the mechanism of reduction of drug resistance of parasites by passage through some other animal requires brief discussion. For example, if an arsenic-fast strain of *Tr. equiperdum* is passed through several rabbits it is apt to loose entirely or in large part for a time at least its resistance to arsenic when returned to the rat. Voegtlin and his associates believe this change may be due to the chemical composition of the medium followed by a change in the sulphydril system of the parasites. They have also suggested that the resistance of trypanosomes to arsenic induced by subjecting the strain for a long time to sublethal concentrations of such orthochinoid dyes like trypaflavin or pyronin, may be due to the fact that these substances can undergo reduction to leuco compounds and the reaction being reversible, may perhaps affect the sulphydril compounds of protoplasm in the same manner as does arsenic.

At any rate these views are good working hypotheses and it is highly probable that the mechanism involved in the resistance of parasites and body cells to one type of drug is likely to be quite different from that concerned with drugs of an entirely different class. It may be stated however, that drug resistance has nothing to do with virulence and that when a parasite acquires the property it is apparently due to some intrinsic change in its protoplasm which is usually transmitted to succeeding generations for prolonged and indefinite periods of time.

Chemical Action of Drugs upon Body Cells and Parasites in Relation to Toxicity and Parasiticidal Activity.—The key-note of modern chemotherapy is the possibility of synthesizing chemical compounds or discovering natural compounds or drugs of either vegetable or mineral nature, capable of selectively destroying the parasitic causes of disease in the body. The dominant idea is that such effects are brought about by some kind of union with the protoplasm of the parasites. Unquestionably toxic effects may be produced by several factors aside from a direct chemical action upon the protoplasm of body cells by the drug, as, for example, the effects produced by intravascular lysis and agglutination of erythrocytes by arsphenamin, but insofar as parasiticidal effects are concerned, the idea of chemical combination with the parasites (bacterial, protozoan or metazoan) predominates in chemotherapeutic research.

But the evidence of such action is very meager. Does arsphenamin and its congeners cure syphilis by a direct toxic action upon the spirochetes by the compounds as injected, or by trivalent oxids of them produced *in vivo*, or by new compounds of them formed by union with some cellular constituents, like Levaditi's liver "trypanotoxyl?" No one has shown this com-

bination with the parasites by chemical analysis, although the work of Voegtlin and his associates on the interaction of arsenic with the SH compounds of trypanosomes is suggestive. Do mercury and bismuth cure syphilis by a direct union of the compounds (presumably in an ionic state) with the spirochetes? No one has demonstrated such, although there is evidence to indicate that mercury at least tends to accumulate in syphilitic tissues. Does iodin cure syphilis by a direct chemical combination with spirochetes? No one has produced the evidence, although it would appear that this agent may accumulate in gummas and aids in the cure of the disease, not by a direct spirocheticidal activity, but rather by reducing the antitryptic activity of the tissue juices by a saturation of the unsaturated fatty acids and thereby promoting proteolytic activity. Does quinin cure malaria by a direct combination with the malarial protozoa? No one has shown this to be the case by chemical analysis. Are the toxic effects of the organic arsenicals, quinin, emetin, the dyes, mercurials, and chemical compounds and drugs as a whole due entirely or in part to a direct chemical union with the body cells in general or those of a particular organ or tissue? The evidence is not clear, not, however, because of negative results from chemical analysis, but simply because the subject has not been investigated sufficiently to warrant an opinion and especially in relation to the question of chemical action and parasiticidal effects. Indeed, the results of chemical analysis of the liver and other organs after the administration of arsenic, mercury, dyes and other compounds does indicate that chemical compounds have apparently united or entered the protoplasm of body cells, although their exact chemical constitution may not be determined. Organotropic and parasitotropic effects of chemical agents due to definite chemical combination with constituents of the protoplasm have not been disproved, and while the acceptance of such a theory is difficult because the same toxic action may be produced by drugs having no chemical reactions in common, yet this should not weigh too heavily against the view that the toxic and parasiticidal effects of some chemical agents and drugs may be due to a definite chemical combination with the affected cells. At least the tendency for some drugs to accumulate in certain cells, the relation between biological action and chemical constitution, the fact that many compounds are altered in the body, as, for example, the arsenicals by processes of oxidation and reduction, tend to confirm this view, although it is freely admitted that these effects may occur as a result of physical properties and that instead of definite chemical combinations merely adsorption occurs; in any event, the combinations may be very very loose and unstable and the effects produced only as the agent passes in or out of the cells.

The subject is one of fundamental importance in relation to pharmacology, toxicology and therapeutic science, long and persistently neglected by the investigator because of the many, great and, at the present time, apparently insuperable difficulties attending investigations along these lines. But the basic idea of pharmacologic action, toxicity and parasiticidal effects being due in part, at least, to definite chemical combination of drugs with protoplasmic constituents has not been disproved by any means, and I believe it is worthy of very serious consideration as a fundamental mechanism. I have already discussed the subject of chemical constitution of compounds in relation to drug fastness, organotropism and parasitotropism, pointing out that changes in chemical constitution may profoundly alter these actions, but this may be not only a result of changes in the physical properties and physical action of the compounds, but also because of an alteration in the chemical affinity of the compounds for some constituents the body cells and parasites.

Physical Reaction and Effects of Drugs upon Body Cells and Parasites in Relation to Toxicity and Parasiticidal Activity.—But while the definite chemical action of drugs upon body cells and parasites bears this important relation to pharmacological, toxicological and therapeutic activities, within recent years there has been a growing tendency to ascribe these actions in whole or in part to various physical properties and action. However, these in turn are usually influenced by the chemical constitution of the drug, thereby preserving in an indirect way the importance of chemical constitution in relation to biological action, but the effects of the drug are ascribed primarily to such physical characteristics as solubility in the blood and tissue juices, solubility in the cells, adsorption by the cells, changes in electrical charge, salt action or penetration of cells with a drug and a consequent alteration of protoplasmic constituents in relation to the surrounding fluids, alterations in surface tension of cells, changes in the cell membranes of body cells and parasites by fat-solvents, protein precipitants, etc.

Probably one of the most important of these physical factors is their influence upon the *permeability and penetrability of cells*. Thus Traube and Matthews state that the capacity of adsorption by the cell substance is of the greatest importance and that every transition causes far-reaching changes. For this reason, even sodium chlorid may become a protoplasmic poison in certain concentrations strongly influencing the colloidal state of the proteins of protoplasm. Adsorption changes consist principally of a sedimentation of colloids with an interaction between the electrical charge of the smallest particles of the cells and precipitating substance, and "as the products of microörganisms probably always will be cationic and anionic, the most favorable effect will be gained by combination of drugs composed of cationic and anionic preparations." As shown by Moldenhauer,[15] in experiments upon the penetration of pentavalent and trivalent arsenic into the wall, protoplasm and sap of *Valonia*, the highest concentration was found in the protoplasm, pointing to a combination of arsenic with protoplasm, but the degree of penetration was least when the external solution was nearly neutral and increased as the H ion concentration became either more acid or alkaline. For example, trivalent arsenic did not penetrate as readily into protoplasm in the acid range as pentavalent arsenic, showing the influence of reaction of the surrounding medium upon the process.

The penetration of dyes and arsenic into the brain and other tissues is likewise apparently influenced by solubility reactions. Ehrlich,[16] for example, stated that neurotropic substances are lipotropic, and Overton[17] believed that before a substance could penetrate into a cell it must be soluble in the cell membrane, and since these membranes were regarded as being lipoidal it should follow that a drug to penetrate must be soluble in lipoid solvents. That this subject is of therapeutic importance is indicated by the experiments of McIntosh and Fildes[18] upon the penetration of dyes and arsphenamin for the brain; these authors were inclined to believe that the absence of arsphenamin in the brain was due to the fact that it was not soluble in chloroform or related substances. Likewise with the dyes the chief factor governing their passage from the blood into the tissues appeared to be a peculiar solubility reaction, but not a question of general lipoid solubility. Langer,[19] for example, believes that the efficacy of a bactericidal agent depends on its power to penetrate the exterior of bacteria and that this in turn is closely associated with its diffusibility and on the electrolytic qualities of the semi-colloidal solution.

The whole subject of solubility and penetration is, therefore, of great interest in relation to chemotherapy and the recent lectures of Hamburger[20]

upon the significance of permeability—problems for the biological and medical sciences, are examples of the increasing interest and importance of these physical or physico-chemical factors in pharmacology and therapeutic science. And permeability and penetration are not only of primary importance in relation to organs and especially foci of infection like streptococcus and staphylococcus abscesses, pneumonic lungs, tubercles, syphilitic deposits, etc., but likewise, and even more importantly, in relation to the penetration of individual cells and especially of the various pathogenic bacteria, molds and fungi, protozoa and metazoa. Indeed, these questions are of fundamental importance in chemotherapy and urgently require systematic investigation.

However, since the influence of physical factors in relation to pharmacological action of drugs are generally well known, they need not be discussed here in detail, although of primary importance in relation to the toxicity of chemical compounds for both body cells and parasites. For example, a large number of chemotherapeutic compounds are administered by intravenous injection and at once the problem of toxic reactions due to physical changes in the blood becomes important. As I shall discuss with more detail in later chapters, it is probable that immediate reactions following the intravenous injection of arsphenamin, mercury and other compounds may be due to intravascular lysis, agglutination or precipitation of plasma proteins and salts. But changes in the cellular membranes of both body cells and parasites with acceleration or retardation of permeability and alteration in electric charges may influence the passage of free ions and either increase or decrease toxicity for both body cells and parasites. These surface forces are in turn greatly influenced by changes in hydrogen-ion concentration, lipoid solvents, salts, etc., with possible changes in the aggregation of the protoplasmic colloids. For example, the action of phenol on bacteria is largely dependent upon its being more soluble in lipoids and in proteins than in water and upon its consequent concentration in organisms. Its parasiticidal activities are decreased, therefore, by any condition which decreases its differential solubility like alcohol, alkali, and oil. The action of the cresols and coal-tar acids appears to depend upon emulsions being absorbed by organisms and the action of mercury and other heavy metals is apparently due to absorption upon the surface followed by penetration into the interior of cells. The effects of electrolytes and proteins in diminishing the oligodynamic or parasiticidal activity of chemical agents are likewise examples of the influence of physical forces as, possibly likewise the effects of chlorin compounds and oxidizing agents due to the union of free chlorin or oxygen with the proteins of body cells and parasites. The effects of mercury, silver and other heavy metals are generally ascribed to ionic dissociation, as originally shown by Krönig and Paul with mercuric chlorid, but differences in degree of ionization will not explain all differences in the disinfectant activity of such compounds; for example, mercuric nitrate and acetate dissociate as freely as mercuric chlorid, but yet these do not possess by any means the bactericidal activity of the latter.

But while pharmacologists have discussed such questions at length in relation to the pharmacological and toxicological actions of drugs, they have not always attempted to explain parasiticidal effects on the same basis. It is reasonable to assume, however, that parasites are subject to the same changes and just as the selective effects of drugs for certain cells are explained on the basis that they are peculiarly susceptible to this or that physical effect and change, so may we assume that it is possible for selective parasiticidal effects to be influenced by similar physical actions. But in the

final analysis it would appear that these physical phenomena are primarily influenced by the chemical state of the protoplasm of body cells and parasites, the surrounding fluids and by the chemical constitution of the drug. As so well stated by Cushny: "These views have all been supported by a certain amount of evidence, and there is every reason to believe that these physical properties are important factors in the action of some drugs. But it is equally obvious that no one of them will explain the whole of pharmacological action, and there is reasonable doubt whether the whole of the physical characters taken together will suffice for this. From the present confusion the only legitimate conclusion seems to be that the activity of drugs depends on a large variety of factors, and that pharmacological action cannot be brought under any one law, either chemical or physical."

McDonagh,[21] however, has attempted to place chemotherapy upon definite physico-chemical laws of oxidation and reduction; for example, in his opinion, the arsenic of arsphenamin does not attack *Sp. pallida* directly, but only indirectly by increasing the oxidizing action of the protein particles in the plasma and cells. McDonagh believes that in chemotherapy metals cause dispersion of the protein particles and non-metals condensation, the former conducting electricity to the particles causing them to increase in number and increasing their negative charge; that the chief protective substance is the protein in the serum, which exists in the form of colloidal particles, each of which has a surface; that the parasitic cell is nothing more nor less than a number of colloidal particles enclosed in a fixed area; that all actions between colloids are surface actions, and the two most important are those of oxidation and reduction; that parasites require oxygen for their existence, and, always living at a disadvantage, must needs protect their oxygen, which they do by exhibiting a prevailing reducing action on their surface; that the colloidal particles of the protective substance (antibody) strive to increase their surface oxygen, which appears to exist in the form of hydroxyl (OH); that as hydroxyl and hydrogen possess opposite electric charges, they will neutralize each other when they meet; that, if, then, the protective substance has an excess of hydroxyl it will destroy the hydrogen on the surface of the parasite, with the result that the latter will die because it will be unable to reconvert the metallic tri-hydroxid into the di-hydroxid or catalytic form; that, therefore, the aim of chemotherapy is to increase the hydroxyl on the surface of the protective substance.

I am stating McDonagh's views much as he has stated them, but my training and experience do not permit me to discuss them, compelling me to merely give the chief principles and some of the references for the aid of those particularly interested in these views, which, at least, have the merit of originality.

Distribution, Storage and Fate of Chemical Agents within the Body in Relation to Chemotherapy.—In chemotherapy, as in therapeutics in general, chemical compounds are not distributed uniformly, but accumulate especially in certain cells, according to chemical affinities or physical forces of which permeability, absorption and adsorption would appear to be of great importance; probably in most, if not all instances, distribution after absorption is the result of a combination of chemical and physical forces, and the aim of chemotherapy is to produce chemical agents possessing a selective affinity for invading parasites with a minimum of affinity for body cells and especially cells of physiological importance whose injury or death would produce lesions and symptoms and prevent the use of the compound regardless of what parasiticidal activity it may possess. In other words, the distribution of a compound in the tissues following absorption after enteral or parenteral

administration is intimately related to its organotropic and parasitropic properties, although both of these in turn are subject to modification by disease states.

But as a general rule, chemical compounds undergo more or less profound changes after absorption and with few exceptions are not eliminated in exactly the same chemical state as when administered. With the metallic compounds like those of mercury, silver and gold, this may amount only to a varying degree of ionic dissociation; but with the dyes and arsenicals, changes of oxidation or reduction may occur profoundly influencing distribution, organotropism and parasitotropism. It is largely for this reason that the results of *in vitro* parasiticidal tests have but little bearing upon possible *in vivo* effects, although a more direct relation exists in regards to the effects of the agent when applied locally to the skin or a mucous membrane under which circumstances there are far less chances for the profound changes occurring after absorption into the blood and other body fluids. Insofar as parasiticidal effects are concerned, the changes *in vivo* may result in an increase of activity as apparently occurs with the organic arsenicals undergoing oxidation or reduction into the trivalent oxids; or a reduction in activity as occurs with practically all the dyes, acriflavin being a possible exception. As a general rule, however, whatever increases toxicity for the parasites also tends to increase toxicity for the body cells, although the ratio may be so much in favor of the former as to endow the compound with therapeutic properties.

As a general rule, the most profound changes occur after absorption. In the gastro-intestinal tract, hydrolysis, saponification and various other changes due to either the acids or alkalies of the stomach and intestines may materially alter a compound, but the important changes of ionic dissociation, oxidation and reduction occur mostly after absorption.

Naturally, the tendency of these forces is always to reduce toxicity for the body cells. The primary change may increase toxicity for both body cells and parasites for a brief time, but the ultimate result is a reduction. For example, the pentavalent and trivalent arsenicals, reduced or oxidized to the toxic trivalent oxids, appear to be finally transformed into more or less inert pentavalent compounds; mercury and many metals are detoxified by union with proteins; phenols and other aromatic compounds by sulphates, etc., the degree and extent of such activities depending upon the activity of metabolic processes and the amounts of neutralizing substances available. The liver and muscles are particularly concerned in disintoxication processes, especially the former for the arsenicals, quinin, the metals, etc., although no symptoms may arise from this organ. It is likely that the liver is involved in this manner largely because of its eliminative functions, just as the kidneys, skin and gastro-intestinal mucosa may be found to contain unusually large amounts of various chemical agents, not because of selective affinities, but because they are brought to them for elimination, during which process, however, and by reason of such function, they may suffer injury, as shown by the effects of mercury upon the gums, lower gastro-intestinal tract and kidneys.

Naturally, these forces influence the concentration of chemical compounds and drugs and our methods of administration. When injected intravenously or absorbed from the muscles or gastro-intestinal tract, they rapidly disappear from the blood and the concentration in the tissues depends primarily upon the dose given, rate of absorption, rate of excretion, rate of change into harmless substances, etc., and the problem in chemotherapy is to raise or maintain a concentration of parasiticidal proportions without injury to the

body. If accumulation occurs in any organ or organs exceeding the rate of elimination, toxic cumulative effects may occur as sometimes met with in the administration of mercury, arsenic, the iodids, etc.; or these and other compounds employed in chemotherapy may cause continually repeated injuries, individually too slight to be noticed, but ultimately producing symptoms as a result of such damage, rather than by accumulation of the compound.

This brings us to a consideration of the question of the therapeutic activity of stored or accumulated compounds so frequently referred to in chemotherapeutic literature as "depots." Does the arsenic stored in the liver during the treatment of syphilis with arsphenamin and its congeners exert spirocheticidal or other therapeutic effects in syphilis? Unquestionably it may injure the liver in the way of producing albuminous and fatty degeneration, but I very much doubt that it exerts a therapeutic effect, as will be discussed more fully in Chapter XII. Does mercury accumulated in a tissue or organ, probably as a loose globulin compound, continue to exert spirocheticidal properties? In my opinion this is highly probable, since it would appear that absorption and dissociation may not be involved. The matter depends therefore, upon the state or condition of the stored chemical agent insofar as therapeutic activity is concerned. Merely because a compound like arsenic is stored, need not necessarily mean that it will exert a curative activity in syphilis when re-absorbed and in the process of elimination. But we have very little information on this subject, although I think the little we have warrants the statement that "depot therapy" may or may not be of value in chemotherapy, according to the compound administered: compounds stored in a therapeutically inert state like some pentavalent arsenicals are probably inert while compounds of the metals like mercury and bismuth, may be active if capable of dissociation upon re-absorption.

Influence of Disease upon the Toxicity and Parasiticidal Activity of Chemical Compounds in Relation to Chemotherapy.—As is well known, various pathological states may profoundly alter the absorption, distribution, elimination and general effects of a chemical compound. This subject is of special importance in chemotherapy, for while the pharmacologist and therapeutist may administer a drug for its effects on healthy tissues in order to relieve the diseased tissue of some or all of its work and to permit it to rest, the chemotherapeutist aims to disinfect the diseased tissue. For example, in valvular disease of the heart, drugs may be given, not with the hope of restoring them to health, but to act upon the healthy heart muscle to correct disturbances of circulation due to the defective valves. But chemotherapy primarily aims to cure the diseased tissue, although it is sometimes resorted to for its general effects, as the administration of neoarsphenamin in the treatment of some of the non-syphilitic anemias.

There is, however, a very peculiar relation between some diseases and the pharmacological and toxicological effects of chemical compounds. For example, the bromids may suppress the convulsions of epilepsy with much less suppression of the brain of normal individuals; digitalis may produce diuresis in cardiac disease but not in health; antipyretics may reduce the temperature in hyperpyrexia but not when the temperature is normal; quinin may produce cinchonism of normal persons in small doses, while malarial and pneumonic individuals ordinarily withstand large doses; the iodids may rapidly produce iodism in healthy persons, while syphilitics can sometimes take enormous doses; tolerance for mercury may be slight in the healthy, while greatly increased in syphilis, and so on through quite a list of examples. In other words, it would appear that the toxic effects of some compounds like the iodids, mercurials and even the arsphenamins, are appreciably reduced by the presence of *Sp. pallida* in the body and that the toxic effects of quinin and related substances are reduced by the presence of the malarial protozoa and pneumococcus just as the virus of acute rheumatic fever appears to greatly increase tolerance for the

salicyl compounds. Why this is so cannot be stated; probably it is due in part to more rapid metabolization of the compounds like the effects of alcohol in hyperpyrexia, or to some peculiar detoxifying influence by products of the parasites. On the other hand, just the very opposite effects may occur with an appreciable reduction in resistance or tolerance to drugs, and especially in acute infections, by reason of a probable reduction in what is commonly designated as "general resistance." For example, white rats heavily infected with virulent trypanosomes cannot ordinarily withstand as much arsphenamin per kilogram of weight as normal rats; in other words, there is a summation of the toxic effects of the infectious products and the drug along with a suppression of vital resistance. Of course, the influence of diarrhea upon reducing absorption when drugs are administered orally by rushing them through the canal to the external world is readily understood; likewise the very opposite to this, when accelerated absorption may occur by more rapid diffusion in diseased intestines; also the increased absorption of some compounds after hemorrhage and especially increased absorption by the meninges and brain following dehydration of these tissues.

When the enunctory organs are involved by disease, there is always an increased danger from toxic effects. For example, the intravenous injection of ordinarily harmless doses of mercury or arsphenamin in the presence of nephritis may result in severe nephritis and anuria; arsphenamin administered to individuals with a damaged liver may greatly increase the chances of arsenical jaundice, just as mercury or bismuth greatly increase the chances of producing siderosis and gingivitis in the presence of pyorrhœa alveolaris.

In other words, the presence of pathological states may profoundly influence the absorption, distribution and elimination of chemical compounds and these in turn their organotropic or toxic effects. In chemotherapy especially these influences must be kept in mind and particularly when physiologically important organs are involved. In a general way, it may be stated that the presence of parasites in the tissues influences the localization of some chemotherapeutic compounds probably by reason of a peculiar chemical or physico-chemical affinity between some protoplasmic constituent and the drug; for example, I have reasons for believing that mercury may especially accumulate in syphilitic tissues even when bone is not involved and certain dyes and other agents are known to collect in tubercles.

This naturally brings up the question of what may be the true value of animal experimentation in pharmacological and chemotherapeutic investigation when normal animals are employed and especially in relation to the toxicity of chemical compounds and drugs, if these effects are so likely to vary among human beings and the lower animals and so subject to modification by diseased states. As stated by Sollmann, "this brings up the fundamental question: To what extent can results observed on animals be transferred to man? The same question applies to all other fields of experimental medical research, and has been abundantly answered by their results" and I shall reserve for the succeeding chapter a more detailed discussion of the subject in relation of chemotherapy.

Influence of Chemical Compounds upon Immunological and Tissue Reactions in Relation to Chemotherapy.—But while the pharmacological and toxicological action of chemical compounds and drugs may be influenced by pathological states, either in the direction of reducing or increasing resistance or tolerance, the influence of drugs upon tissue reactions about areas of infection may have a beneficial influence with an increase of parasiticidal activities. I refer to the possibility of increasing hyperemia, leukocytic infiltrations and the laying down of fibrous tissue, known as the *dynamogenic activity* of chemical compounds and believed to be of beneficial influence in such diseases as tuberculosis and syphilis by reason of circumscribing the infection, shutting off oxygen and food supplies and allowing the acid and other waste products of the organisms to accumulate and gradually

bring about their destruction. It is sometimes stated that arsenic may exert beneficial effects of this kind; that gold compounds may produce hyperemia about tubercles resembling the tuberculin reaction and that various substances like cinnamic acid, phosphorus, nucleinic acid and silicic acid may excite inflammation and promote mineralization of the tissues of tubercles.

Of equal importance is the possibility of some compounds uniting with cellular constituents and forming actively parasiticidal compounds. Levaditi and Yamanouchi, for example, believe that arsphenamin and other therapeutically active arsenicals owe their efficacy to the production of active compounds with liver cells and the whole subject of an important synergistic activity on the part of tissue constituents, with the production of new compounds of enhanced parasiticidal properties, is worthy of consideration, although the direct evidence in view of this hypothesis is meager at best and largely based upon the assumption that such combination products must be produced *in vivo* to which therapeutic activities may be ascribed.

But the influence of chemical compounds upon chemotaxis, phagocytosis and other immunological processes has long commanded most attention in relation to chemotherapy. These effects may be due, however, to two entirely different mechanisms, namely, (*a*) the possibility of chemical agents destroying parasites and thereby liberating antigenic substances capable of engendering antibody-production and (*b*), the possibility of the agents directly stimulating the antibody-producing tissues. Ehrlich always maintained that the former process was of importance in chemotherapy and that chemical agents may release antigenic substances from parasites with increased antibody-production, or so far devitalize organisms and especially their proliferative activities, that natural or acquired immunological principles were enabled to finish the job of destruction. Ehrlich [22] also thought that these effects may bring about paradoxical results if large numbers of parasites were suddenly destroyed with the release or production of large amounts of toxic substances producing what he termed "*effectus contrarius.*"

Needless to state, any chemical compound producing leukocytosis may increase the parasiticidal activities of the blood and especially if phagocytosis were promoted. Probably the beneficial effects of mercurochrome by intravenous injection in staphylococcus and streptococcus septicemias may be due in part to the induced leukocytosis and the release of proteolytic and lipolytic ferments from these cells. In the chemotherapy of localized infections, the influence of chemical compounds upon phagocytosis is of particular importance, as it is so easy for drugs to paralyze the phagocytic activities of microphages, macrophages and clasmastocytes instead of promoting phagocytosis. As shown by Felton and Dougherty,[23] with four cinchona derivatives injected intraperitoneally in mice, a chemical agent may be chemotactic and increase leukocytic exudation, but yet prove antiphagocytic and therefore actually harmful. In my experience, however, drugs capable of paralyzing leukocytes are generally somewhat stimulating in higher dilutions.

It is also important to bear in mind the possibility of chemical agents reducing parasiticidal effects by a destructive action on complement and various lytic types of antibodies in the blood and especially in tissues being treated by local applications. The whole subject is one of commanding interest and in the following chapters I shall refer to the influence of various chemotherapeutic agents upon immunological processes in a discussion of the mechanism of their parasiticidal activities.

But can it be said that chemical agents are capable of stimulating antibody-production by a direct action upon the antibody-producing tissues?

It is commonly stated that arsphenamin and mercury cure syphilis by stimulating antibody-production. I believe it is possible that these drugs owe part of their curative activity in syphilis to bringing about the destruction of *Sp. pallida* with the release of antigenic substances from them, but I have had no direct or convincing evidence at all that any chemical compound or drug is capable of actually increasing antibody-production by a direct stimulation of the antibody producing tissues, although they may increase the numbers of leucocytes in the blood and around disease foci with a possible release of enzymes capable of producing therapeutic effects, as Bergel[24] has suggested in tuberculosis in reference to the release of lipolytic enzymes from lymphocytes, which might be imagined to increase the vulnerability of tubercle bacilli to destruction by hostile drugs or other substances.

Combined Action of Drugs in Relation to Chemotherapy.—Related in a general manner to these subjects of the mechanism of toxic and parasiticidal activities of chemical compounds and drugs and especially of drug fastness, is this subject of the combined action of drugs. It is, indeed, an old and much discussed subject in therapeutics but has been revived within recent years in relation to chemotherapy. As stated by Ehrlich, the principle of combination chemotherapy, "is to attack the enemy simultaneously from two or three sides, and thus to produce a completely successful result by the combination of several different substances, each of which alone does not show a sufficient effect. Thus it has been found by Laveran and by Franke that certain infections which are influenced neither by trypan-red nor by atoxyl alone, can be cured if these two substances are used in conjunction. I, too, have in course of time repeatedly met with similar cases, and am convinced that substances which by themselves are not very efficient, may yet produce good results if they are used as adjuncts to those more powerful, though not completely curative, substances. Supposing, for example, a highly trypanocidal remedy to kill ninety-eight among one hundred parasites; its administration would be followed by an instantaneous improvement, but not a definite cure, since the two surviving trypanosomes must in course of time produce a relapse. But if one combined this powerful remedy with another which, even though much weaker, yet sufficed to kill just those two surviving but attenuated parasites, then such a combination would serve to bring about the otherwise unattainable cure."

At another time, Ehrlich stated that the principle of combination chemotherapy is to "march separately, strike combined," and that in this connection "it must be observed that for the combination therapy such drugs must be chosen which will find in the parasite various chemoceptors. For instance, it would be purposeless to employ two arsenicals with bi- or tri-valent arsenic; also fuchsin should not be combined with the allied methyl-violet, as the same receptors are present, but the fuchsin bodies should be combined with arsenicals. Two different remedies may eventually be introduced in very small quantities into the organism without harming it and also without losing their parasiticidal qualities. On the contrary the relation between the curing dose, *dosis curativa*, and the toxic dose, *dosis toxica*, becomes much more favorable and far smaller than when the single remedies enter into action each by itself. By such a combination of different classes or types of dyes and arsenicals which have also a different distribution, the principle of marching 'separately and striking combinedly' is put into effect. Especially such drugs should be chosen which attack the two cell constituents, nucleus and protoplasm, separately."

Furthermore, it would appear that under combination therapy, drug fastness may be overcome in practical therapeutics and may be even made to

disappear if one may accept reports indicating that patients with malaria treated with quinin and rendered quinin-fast were later found sensitive to quinin after treatment with arsphenamin. In syphilis it is possible that the spirochetes may acquire fastness to the arsenicals but remain sensitive to the mercurials or bismuth and the reverse.

Another example of combination therapy is the treatment of bacterial infections with immune serum and chemotherapy, known as chemoserotherapy.

Numerous additional examples of combination chemotherapy may be cited and especially in the treatment of trypanosomiasis with the arsenicals and antimonyls; the treatment of syphilis with the arsenicals, mercurials and bismuth salts; the treatment of malaria with the cinchonics, arsenicals and methylene blue, etc., but I shall return to the subject in later chapters upon the chemotherapy of these and other diseases.

Naturally Ehrlich considered combination chemotherapy a complete support for his theory of chemo-receptors, but this is not necessarily so since it would appear easily possible for chemical agents of similiar parasiticidal properties to attack along the chemical or physico-chemical lines discussed above. Neither is it a justification for the use of indiscriminate and "shot-gun" mixtures in therapeutics, since in chemotherapy combination therapy is strictly limited to the combined use of the fewest possible drugs known to possess some degree of specific curative effect for the disease under treatment. As a general rule, the compounds are administered separately but may be mixed together before injection, as in mixtures of neoarsphenamin and mercuric chlorid, with the possibility of forming new compounds either before or after administration with synergistic effects. On the other hand, due care must be exercised against the adoption of incompatibles and antagonistic combinations. As a general rule, it would appear that combination therapy in chemotherapy is usually a simple algebraic summation of the effects, but not infrequently the results cannot be explained on this basis and a potentiated effect is observed. The mechanism of potentiation has not yet been elucidated although Buergi's law[25] would appear applicable to some of the phenomena, namely, that potentiation occurs always and only, when two compounds have different points of attack in the cell because two different receptors take up more poison in a given time than could a single receptor from a double quantity of a single compound. Naturally, Ehrlich was inclined to accept this theory since it called into play his own theory of chemo-receptors, but I believe the subject may be reduced to a simple chemical or physico-chemical proposition in which two or more drugs may find in the same parasite protoplasmic constituents for which they have a chemical affinity and with which they may interact independently of each other; or two or more compounds may interact before or after reaching cells with the production of new compound capable of chemical or physico-chemical interaction with protoplasmic constituents. From the standpoint of chemotherapy, combined therapy to be useful must have more parasiticidal effects than either drug alone without, however, an increase of organotropic effects.

Summary of the Nature and Mechanism of the Toxic Effects of Chemical Agents and Drugs for Parasites and Body Cells.—It is apparent, therefore, that chemotherapy has developed into a far more complex subject than originally conceived by Ehrlich, with a need for modifying the theoretical structure upon which it was based. The ideal and aim of producing chemical agents capable of selectively disinfecting the tissues without harm to the host remains unchanged, but I have all but abandoned the hope of accom-

plishing this on the basis of the chemo-receptor theory. Complex chemical and physico-chemical forces are involved in the effects of a chemical agent on both body cells and invading parasites and the matter of selective destruction of parasites in the tissues would appear to be one of chemical or physico-chemical interaction between the chemical agent and protoplasmic constituents of the parasites, just as the specific immunological processes of the body are being gradually placed on the same basis.

Instead of conceiving a remedy killing invading organisms by direct union through the agency of theoretical chemo-receptors, a broader and more comprehensive conception is required to explain the observed phenomena, as a remedy not acting as such, but in virtue of the formation from it in the body of some directly toxic product, either by a modification of its structure or by its union with some tissue constituent; of modifications of virulence and a reduction of resistance with increased susceptibility to destruction by the body's natural defenses, the *mechanism of parasiticidal activity* calling into play any one or several of the following factors depending upon circumstances and discussed above in detail:

1. A direct chemical interaction between the compound or drug as administered or after some transformation in the body, with some protoplasmic constituent of the parasite, resulting in the death or crippling of the latter by interference with its vital processes as those of alternate oxidation and reduction (internal respiration).
2. A physical or physico-chemical interaction with the protoplasmic colloids of parasites involving precipitation, coagulation, changes in electrical charge, etc., sufficient for destruction or crippling.
3. The possible production of new compounds in the tissues capable of chemical or physico-chemical interaction with protoplasmic constituents of invading parasites rather than the production of these effects by the compound direct as administered.
4. The possible production of antibodies by releasing antigenic substances from the parasites.
5. The stimulation of processes of oxidation; the production of hyperemia and stimulation of reparative processes; the production of leukocytosis and mobilization of proteolytic, lipolytic and diastatic enzymes capable of interfering with the nutrition or otherwise crippling invading organisms, etc.

And the *mechanism of organotropic or toxic effects* of chemical agents for the body cells in general or of a particular group, is likewise far from being the simple matter of union by chemo-receptors, involving as it does the subjects of absorption, elimination, distribution, fate and other complex pharmacological and toxicological effects, the production of toxic lesions and symptoms being by one or more of the following processes:

1. By immediate reactions in the blood like agglutination or lysis of erythrocytes, precipitation of plasma proteins or salts, with the production of colloidal shock reactions, embolism, etc.
2. By direct chemical interaction between the compound or drug as administered or after some transformation in the body, with some protoplasmic constituent of the fixed body cells and resulting in the death or crippling of the latter by interference with vital processes. Or by some physical or physico-chemical interaction with the protoplasmic colloids of cells involving precipitation, coagulation, changes in electrical charge, etc., either mechanism involving the body cells as a whole or particular groups and centers by reason of special affinities or through the function of elimination.
3. By producing excessive hyperemia, cellular infiltrations, and other tissue changes; by promoting excessive enzymic activity with the production of toxic substances from dead or devitalized body cells or parasites; by promoting or stimulating the activities of parasites, as in the Jarisch-Herxheimer reactions of syphilis, etc.

A study of the toxicity of a chemical compound or drug, therefore, in relation to chemotherapy, may be not only a matter of simply determining the minimal lethal or maximal tolerated doses per kilogram of body weight for the lower animals, but under certain circumstances involves a study of

its pharmacological and toxicological effects for human beings and especially for sick human beings, which brings into play far more complex processes than met with in healthy lower animals; but this is a large and important subject which may be taken up in the succeeding chapter.

CHAPTER II

METHODS FOR DETERMINING THE TOXICITY OF CHEMICAL AGENTS IN RELATION TO CHEMOTHERAPY

Unfortunately, the biological properties of a compound or drug, that is, its pharmacological, toxicological and parasiticidal activities in the body, cannot usually be determined by chemical analysis alone; as a general rule, these are ascertained empirically or by tests employing the lower animals. It is true, however, that chemical analyses are frequently helpful in these respects; for example, to know beforehand the amount of arsenic present in an arsenical compound or the amount of mercury present in a mercurial compound, etc., will sometimes enable one to estimate the probable toxic doses for the lower animals, but such information is seldom acceptable in lieu of actual toxicity tests. This is particularly true of complicated organic compounds; no matter how carefully they are prepared and that analyses indicate that several of a kind are apparently identical in chemical constitution, rigid animal tests sometimes show existing variations in toxicity and to a lesser extent of parasiticidal activity.

Empiricism in Relation to Chemotherapy.—But before entering upon a discussion of the value and limitations of animal experimentation in relation to chemotherapy, it may be well to briefly refer to the rôle of empiricism in

the same relation. Merely to mention that empiricism alone gave us quinin for malaria, mercury for syphilis, the salicyls for acute rheumatic fever, ipecac and emetin for amebiasis, tartar emetic for kala-azar and other forms of leishmaniasis, chaulmoogra oil for leprosy, etc., is sufficient for indicating the very important rôle it has played in the development of chemotherapy.

It is entirely likely as stated by Dale[1] that empiricism will continue to be an integral part of chemotherapeutic advance and under certain conditions is indispensable. When new compounds are synthesized, they should not be administered to human beings until some adequate idea of their toxicity has been gained by administration to the lower animals and especially if intravenous injections are to be given. To rush a new compound into clinical use before its toxicity at least has been estimated by such preliminary tests is frequently dangerous and always unnecessary and reprehensible. But after this has been done and a compound has been used clinically for the treatment of a given infection, there is no harm in trying it in the treatment of another disease and especially if it is caused by a biologically related parasite. Furthermore, some diseases of human beings cannot be reproduced or duplicated in the lower animals and preliminary parasiticidal tests, therefore, are sometimes impossible; but this does not contra-indicate the use of the compound clinically, provided always that we know in reasonably accurate terms the toxicity of the compound so that one may proceed on the basis of possibly securing a good therapeutic result while doing no harm. In other words, we are never justified in administering a new and unknown compound to human subjects for the treatment of disease, until its capacity for harm has been first determined with reasonable accuracy; on the contrary, however, with such information at hand, we are frequently justified in using it empirically before its possible therapeutic effects have been determined, as this may be only possible by actual administration if the infection cannot be reproduced satisfactorily in the lower animals. Furthermore, there are some rather sharp limitations to the value of pharmacological, toxicological and parasiticidal tests employing the lower animals which may be now discussed with more detail, but the fact requires emphasis that valuable information on the matter of toxicity is always to be gained by properly conducted tests among the lower animals and that no compound potentially harmful should ever be administered to human beings until such tests have been conducted.

Value and Limitations of Experimental Pharmacology in Relation to Chemotherapy.—Usually it is only after a new compound has been quite thoroughly studied from the standpoint of toxicity and therapeutic activity in the lower animals and has found a place of usefulness in the treatment of disease, that its pharmacology attracts attention. But knowledge bearing upon its absorption, fate and excretion, as well as its effects, if any, upon the higher and important centers, heart, etc., becomes indispensable for rational therapeutics; for determining these and related questions, experimental pharmacology may render valuable services.

But great care must be exercised in applying the results of experimental pharmacology to man. Differences in the physiological functions of the lower animals, natural resistance and individual idiosyncrasies, seasonal variations, temperature and diet may have a marked effect on the resistance of the lower animals, as I shall discuss shortly with more detail in relation to toxicity tests; but, as stated by Sollmann,[2] in the hands of the expert pharmacologist, errors of interpretation of results due to these and related subjects are not likely to occur.

As stated in the preceding chapter, pharmacology and chemotherapy are inseparately united, the former being in a way the parent of the latter. I shall, therefore, in later chapters aim to present the pharmacology of the more important chemical compounds and drugs employed in chemotherapy as this knowledge is of the greatest value in therapeutic science; and not a small part of this knowledge has been gained by animal experimentation, although in this treatise the technic of pharmacological methods need not be described, as these are highly specialized and are to be found in text-books devoted to experimental pharmacology.

Value and Limitations of Parasiticidal Tests with the Lower Animals in Relation to Chemotherapy.—While chemotherapy has been applied empirically in the treatment of some metazoan diseases, yet, from the standpoint of the treatment of experimentally produced infections in the lower animals, most investigation has been devoted to protozoan and bacterial diseases and especially those produced by various pathogenic trypanosomes and spirochetes.

Indeed, the discovery of methods of producing experimental trypanosomiasis in mice and rats by Mesnil and Brimont gave great impetus to the original investigations of Ehrlich, Bertheim, Hata and their associates; this was soon followed by the adoption of experimentally produced spirochaetic infections, notably spirillosis of chickens, relapsing fever of mice and syphilis of rabbits, all of which have proved of the utmost value in chemotherapeutic research and contributing in a very essential and important manner to chemotherapeutic discoveries in dye and arsenical compounds. During the past ten years, additional methods have been worked out for the production of other protozoal diseases, as well as of numerous bacterial diseases, so that experimental infections of the lower animals have proved indispensable and capable of yielding information of paramount importance in chemotherapeutic investigations and the practical treatment of disease of human beings. Indeed, it may be stated, that without animal experimentation many of the present great discoveries in chemotherapy could not have been made and notably of arsphenamin and its allied compounds for the treatment of syphilis, frambesia and other diseases; without it chemotherapeutic research would be seriously crippled and rendered all but sterile along with the regrettable rushing of new compounds into the treatment of sick human beings without any preliminary knowledge of their capacity for either harm or good. Furthermore, and properly so, the lower animals themselves have greatly profited by much of this experimental work among them, as several remedies have been found of practical value in the treatment of their diseases, as I hope not to overlook describing in subsequent chapters. While it cannot be denied that empiricism has given us many chemotherapeutic remedies of great value, as discussed above, yet only scientific and well regulated chemotherapeutic investigation can be confidently expected to contribute most advance in the future, of which no small part will be well-conducted animal experiments for determining the possible curative effects of new compounds as they are produced.

Even *in vitro* parasiticidal tests have proved of value, in spite of well-defined limitations and especially in relation to the chemotherapy of bacterial diseases, but the technic of these as well as of trypanosome and spirochetic tests and infections will be described and discussed with more detail in later chapters, as the subjects are too lengthy and important for brief consideration in this place.

Value and Limitations of Toxicological Tests with the Lower Animals in Relation to Chemotherapy.—In this chapter, I wish especially to consider the value and limitations, as well as the methods, for determining the toxicity of chemical agents and drugs for the lower animals in relation to chemotherapy. Without doubt, differences in the physiological functions of such lower animals as white mice and rats, guinea-pigs, rabbits, cats and dogs employed in toxicity tests do not ordinarily permit one to determine all of the toxic qualities of a compound for man, yet the chief toxic effects are readily elicited and a good idea gained of the toxic dose per kilogram of weight which usually yield a safe guide to dosage in administration to man. This has been found true of the organic arsenicals, so that an official rat test for toxicity is required of arsphenamin, neoarsphenamin, sulpharsphenamin,

etc., although rats do not show some of the early or immediate toxic reactions like the "nitritoid crisis," nausea and vomiting, sometimes following intravenous injections of these compounds. Doubtless, this is due in part to the absence of imagination and nervous apprehension on their part which may play an important rôle in the production of apparently toxic reactions in human beings.

Nevertheless, the fact remains that the value of toxicity tests among the lower animals is limited by differences in physiological function and this in turn is influenced by the species employed, age, weight, sex, seasons and diet, as I shall shortly discuss in the following section dealing with methods. For example, the mouse can usually stand more arsphenamin and allied compounds per gram of weight than the rat and both of these more than the rabbit and dog. I believe that this is also true of the organic mercurials and that it can be stated as a general rule that human beings cannot stand nearly as much of these compounds per gram of weight as the rat. In other words, the larger and heavier our test animal, the less is its tolerance, which does not bear a strict relation to body weight.

Furthermore, our test animals are usually normal and healthy which naturally yields a greater resistance to the toxic effects of chemical agents than diseased animals and human beings. Rats infected with *Tr. equiperdum*, for example, frequently cannot withstand as large doses of arsphenamin or neoarsphenamin per kilogram of weight as normal rats. Doubtless, the occurrence of toxic reactions from arsphenamin and allied compounds in human beings is sometimes due primarily to underlying pathological states produced by syphilis or some other disease materially altering the metabolization and excretion of the drug with an increase of toxicity.

But despite the influence of species and racial idiosyncrasy in the lower animals, of size and weight, general conditions of health, diet, sex, etc., experience has shown, as stated by Sollman: "*If a given poison affects all species alike, it may be concluded that its action on man is also the same.* If it produces different effects, but if these can be explained by differences in physiology, the effects on man will be similar to those produced on the species the physiology of which resembles most closely of man."

Maximal Tolerated and Minimal Lethal Doses of Compounds in Relation to Toxicity Tests.—As a general rule, toxicity tests with the lower animals aim to elicit the following data: (1) The largest amount of drug per kilogram of weight compatible with life for a stated period of time and designated as the *maximal tolerated dose* (M.T.D.); (2) the smallest amount of drug per kilogram of weight producing death at once or within twenty-four hours and designated as the *minimal lethal dose* (M.L.D.); (3) whether or not acute symptoms or "early reactions" are produced, and (4) whether or not pathological changes in the tissues are produced and largely responsible for the "late reactions."

All of these and especially the first three, are influenced to some extent by the animal employed, the route of administration, the concentration of the solution of compound, the rate of its injection, if by the intravenous route, and numerous other factors. In other words, the M.T.D. and M.L.D. of any given compound are by no means fixed values and the same or approximately the same figures with the same compound tested in different laboratories are to be secured only by adhering strictly to a standard technic. For these reasons the Hygienic Laboratory of the United States Public Health and Marine Hospital Service has laid down a detailed method for the testing of arsphenamin and allied compounds employed in this country and somewhat similar regulations are in force in England and elsewhere.

As a general rule, the maximum tolerated dose of a compound is, by all odds, the most important value in relation to chemotherapy and is practically always less than the minimal lethal dose. It is determined by giving a series of rats or other animals, of approximately the same age, weight and general condition, single doses of increasing amounts per kilogram of weight of a solution of stated concentration at a stated rate and stated route, to determine the largest amount per kilogram borne for ten days to two weeks by at least 60 per cent. of the animals injected. Duration of life is practically the sole criterion and at least ten days are allowed for the production of late effects; two weeks is a better interval for most compounds and especially for the arsenicals and mercurials. The maximal tolerated dose may be likewise determined by giving a series of administrations at stated intervals over a given period of time, but the results are not as sharp and clear cut as when single doses are injected.

The minimal lethal dose is determined in the same manner and represents the smallest amount per kilogram of weight proving fatal for at least 60 per cent. of animals at once or within an arbitrary period like one to twenty-four hours after administration. As a general rule, only single doses are given, but it is to be emphasized that the figures are of scientific value only when a uniform method is employed, since details, often those appearing but trivial, may exert an important influence upon the results. For these reasons, the data on toxicity of compounds given in subsequent chapters can be regarded only as approximately correct, because they have been based upon quite a variety of different methods employed by many investigators.

Factors Influencing Toxicity and Therapeutic Tests in the Lower Animals. A considerable amount of our information bearing upon toxicity tests in relation to chemotherapy has been gained from studies upon the toxicity of the organic arsenicals, and especially arsphenamin and its congeners, for mice, rats, guinea-pigs and rabbits. Of course, pharmacologists have employed some of these animals, and more especially dogs, for toxicity tests for many years, but the advent of arsphenamin and its allied compounds and the necessity for checking and controlling their toxicity, trypanocidal and spirocheticidal properties, has resulted in a much wider employment of toxicity and parasiticidal tests in laboratories engaged in the preparation of these and other chemotherapeutic compounds.

Choice of Animal.—For pharmacological studies upon the influence of drugs upon the heart and circulation, respiration, etc., the dog would appear to be mostly employed, with the cat or rabbit as second choice. But for routine toxicity, trypanocidal, spirocheticidal and bactericidal tests in relation to chemotherapy, the white mouse (*Mus musculus albus*), white rat (*Mus Norwegicus albus*), guinea-pig and rabbit are usually employed. Ease of handling, costs, cage space, whether multiple intravenous injections are to be given, etc., are factors sometimes influencing the choice.

On the whole, I believe that the *white rat* of 100 to 200 grams weight is the best animal of all for routine toxicity and trypanocidal tests. This is true at least in the testing of arsphenamin, neoarsphenamin and allied compounds in which I have had most of my experience. I have also employed rats in toxicity tests with various dyes, cinchonics, organic and inorganic mercurials and numerous organic compounds of other heavy metals, with uniform satisfaction. Indeed, a rather extensive experience during the past eleven years with toxicity and various parasiticidal tests employing rabbits, guinea-pigs, rats, and mice, has convinced me that the white rat is the best animal of all and especially when a good healthy stock is available.

Influence of Diet and General Care of Animals.—In 1910, Hunt[3] found that the susceptibility of rats, mice, and guinea-pigs to certain poisons was profoundly altered by comparatively slight changes in diet. Lake[4] has stated that rats fed on a well-balanced ration and in a good state of nutrition will tolerate a higher dose of arsphenamin or neoarsphenamin, and react more uniformly than poorly nourished animals. Hooper, Kolls and

Wright,[5] Roth and I have also observed that diet was important in securing constancy in the results of toxicity tests in rats with arsphenamin and allied compounds.

As stated by Lake, the health and general nutrition of rats are important factors in resistance to arsphenamin and in his opinion, variations in susceptibility in rats from different colonies or dealers are due solely to differences in the health and nutrition of the animals. Differences in the toxicity of lots of arsphenamin amounting to as much as 20 per cent. were ascribed to these factors.

Lake also observed that rats after feeding may be 10 per cent. heavier and that if used for toxicity tests, may receive an excessive dose according to body weight. He also found them somewhat more susceptible to arsphenamin after a meal, which is borne out by clinical experience showing that patients are more liable to react on a full stomach. For these reasons, rats should not have access to food for at least twelve to eighteen hours before being injected with any compound.

Rats breed rapidly, are clean and easily kept clean, inexpensive to maintain in large numbers, easy to handle and comparatively easy to treat by any route of administration. Donaldson[6] has published a most interesting and instructive book on this valuable laboratory animal containing information on its life history, feeding, watering, general care, etc. Osborne and Mendel[7] state that partly colored rats may give inconstant results; my experience agrees with that of Roth,[8] that they are generally more resistant to arsphenamin and neoarsphenamin than those entirely white. The diet of rats may consist of white bread, cow's milk, cracked corn, oats, and, in addition, twice weekly, fresh beef and cabbage, or spinach, carrots, etc. Further suggestions in their feeding and care have been made by King,[9] Slonaker[10] and Ferry.[11]

White mice may be given a diet quite similar to that of rats, consisting of a liberal supply of cow's milk, white bread, and a mixture of cracked corn, oats, and sunflower seeds with plenty of fresh water.

The care of the *guinea-pig* differs slightly from that of the mouse and of the rat. The instructions issued by Lantz[12] state that improper, irregular, and deficient feeding are common causes of inflammation of the stomach and intestines, from which losses among the animals may be very great.

Influence of Age, Weight, Body Surface, Blood Volume and Metabolism of Animals.—As shown by Roth[13] in experiments bearing upon the influence of the age and weight of white rats upon the toxicity of arsphenamin and neoarsphenamin administered by intravenous injection, animals weighing from 73 to 98 grams were more resistant than animals weighing from 180 to 275 grams, and largely on the basis of his investigations the Hygienic Laboratory requires that rats employed for toxicity tests with the arsenicals shall weigh from 100 to 150 grams in order to minimize variations due to these factors. According to Donaldson, albino rats which have developed normally and which range in weight between 100 and 150 grams, are from two to five months old. Donaldson's figures from the Wistar Institute colony show that at two months of age, the males averaged 123 grams and the females 107 grams, while at three months of age the males averaged 185 grams and the females 148 grams. On the other hand, the figures which he gives for the New Haven Colony of the Connecticut Agricultural Experiment Station show that at two months of age the males averaged 97 grams and the females 89 grams; at three months of age the males in the same colony averaged 144 grams and the females 115 grams, while females which averaged 150 grams were 150 days old (five months). From the above data, it would appear that normal rats which range in weight from 100 to 150 grams are at least two months and not over five months old, and that a female of 150 grams is considerably older than a male of corresponding weight. Both males and females are sexually mature at two months of age and growth is quite rapid about this period. It is thus seen that the Hygienic Laboratory test requires that the rats used for the special tests on arsphenamin shall be young, sexually mature, and in an active period of development.

Hammett and Nowbrey[14] also found that with advancing age there is a progressive diminution in the resistance of the albino rat to death from arsenic poisoning. A dose of 11 mgm. or over of arsenic trioxid is fatal to young rats of 60 to 90 days of age. By the time the animals have reached the age of 120 to 150 days a dose of 9 mgm. is fatal. When they are 210 to 240 days old, 8 mgm. is the amount which produces death within twenty-four hours in the average animal.

My own results have not shown very striking differences in toxicity tests with arsphenamin and neoarsphenamin, insofar as rats weighing from 90 to 190 grams were concerned. For example, of 358 rats weighing from 90 to 125 grams, injected intravenously with arsphenamin (0.100 gm. per kilo) in 2-per cent. solution at the rate of 1 c.c. in two minutes, 213 or 59 per cent. survived forty-eight hours; of 131 rats weighing from 130 to 150 grams, 94 or 71 per cent. survived; of 37 rats weighing from 160 to 180 grams, 25 or 67 per cent. survived. Of 399 rats weighing from 90 to 125 grams and receiving intravenous injections of neoarsphenamin (0.200 gm. per kilo) in 4-per cent. solution at the same rate, 314 or 78 per cent. survived seven days; of 147 rats weighing from 130 to 150 grams, 116 or 78

per cent. survived seven days and of 46, weighing from 160 to 190 grams, 36 or 78 per cent. survived. Therefore, differences in age and weight influenced tolerance for arsphenamin to a greater extent than tolerance for neoarsphenamin.

Of course, age and weight of human beings greatly influence dosage in chemotherapy, as I shall discuss shortly, but here it is of interest to inquire into the mechanism and nature of the variations due to these factors. Hammett and Nowbray have expressed the opinion that differences in resistance of man and rat to arsenic can be attributed in large part to a difference in the respective rates of protein metabolism. With advancing age, the active mass of protoplasmic tissues and blood volume decrease and probably signify a decreased capacity for dealing with toxic agents. Dreyer and Walker [15] state that the concentration of drugs and other foreign substances distributed in the blood plasma is proportional to the body surface, since blood volume is proportional to the body surface according to the formula $B = W\frac{n}{k}$, where n is approximately 0.72, and k is a constant to be ascertained for each particular species of animal. The same apparently applies to internal surfaces, such as that of the alimentary canal, since Moore[16] came to the conclusion that, in regard to drugs, tolerance was limited by the surface area of the mucous membrane of the alimentary canal, offering a valid explanation of the fact that it is often difficult or impossible to administer effective doses of drugs to large animals, since they do not tolerate doses required to produce the same concentration in their blood as is needed for successful therapeutic action in small animals. Dreyer and Walker, after analyzing the toxic doses of arsenicals, toxins, and other substances, have reached the conclusion that in animals of different sizes in any given species, the dose required to produce a given effect is related to the body surface and blood volume of the animal and not directly to the body weight; that is to say, smaller individuals require a relatively larger dose than the heavier animals to produce the same effect. They believe it follows that in the accurate measurement and standardization of toxic substances and antitoxins, it will now be possible to make use of animals of different weights within a given species, instead of using only animals of an arbitrarily selected weight. The influence of age, weight, blood volume, etc., upon the parasiticidal activity of chemical compounds has not been the subject of as much interest and investigation. In my experiments with *Tr. equiperdum* infections of white rats varying in weight from 80 to 260 grams, no constant variations in the trypanocidal effects of arsphenamin and neoarsphenamin have been noted. I believe, however, that age and weight of rabbits may influence the results of spirocheticidal tests, but largely because these and related factors influence the susceptibility and resistance of these animals to *Sp. pallida*. In other words, age, weight and related factors may influence the course of an experimental infection by bringing into play variations in immunological resistance, but they do not appear to appreciably influence directly the parasiticidal activity of chemotherapeutic agents. While the rabbit and guinea-pig infected with virulent trypanosomes are more difficult to cure than infected mice and rats, yet this does not involve the factors of age and weight, but, rather, the subject of variations due to animal species.

Influence of Species and Individual Variation.—In other words, results in dosage calculated for one species of animal cannot directly be applied to another species merely by taking surface and blood volume into consideration, since tolerance and intolerance are specific characters shown to be in many cases independent of the size of the species concerned. This factor limits, therefore, the usefulness of data on the toxicity of drugs for the lower animals as applied to human beings. I have already mentioned that tolerance of the rabbit for the arsenicals is appreciably less than for the rat as reported by Schamberg, Raiziss and myself,[17] and I believe this is due more to variation in specific tolerance than to age, weight, body surface, blood volume or variations in metabolism. Clinical experience also indicates that the tolerance of human beings as a class for the arsenicals is less than that of mice and rats and probably more closely approaches that of the dog and rabbit.

Individual variations in tolerance are also sometimes striking and not to be explained on these factors of body surface, blood volume and rate of metabolism. They are encountered not only among human beings, but also among rats and rabbits, as reported by Roth,[18] Lake and others. No matter how uniform the stock of rats, or how carefully they are selected, it is impossible to secure uniformity of results within narrow limits, without using a considerable number of animals with the same dose. For this reason it is almost impossible to define sharply the maximum tolerated dose of a compound per kilogram of weight, but we must rather express it as the maximum dose allowing a majority of animals to survive for a stated period of time.

Influence of Sex of Animals.—According to Lake, *pregnancy* of albino rats tends to reduce their resistance to arsphenamin. Since the pregnant uterus of these animals may constitute as much as 10 to 25 per cent. of the entire body weight, it is obvious that if such an animal receives a dose based on body weight, the maternal blood will contain a relatively

larger amount of the drug than that of a non-pregnant animal of the same weight. There is also the possibility that pregnancy itself affects susceptibility in some degree, although we have no data on this point. Since it is difficult to determine pregnancy in a rat from the appearance of the animal alone, unless the condition is moderately advanced, it is important to conduct a necropsy on every animal succumbing, and in case pregnancy appears to have influenced the result, the test should be repeated. Rats of 100 to 120 grams in weight are only occasionally found pregnant, but the most satisfactory method for avoiding the difficulty consists in separating the females from the males, when they have reached a weight of 80 to 90 grams.

Otherwise, sex does not appear to appreciably influence the tolerance of the lower animals for chemical agents. My own experience has been of a similar character, but if differences do exist, the non-pregnant female rat is probably slightly more resistant than the male of similar weight; for example, of 327 male and 325 non-pregnant female rats of 95 to 150 grams used in testing the toxicity of 71 different lots of arsphenamin in dose of 0.100 gm. per kilogram, 76 per cent. of the males survived and 85 per cent. of the females; of 432 males and 320 females of similar weight range used in testing the toxicity of 66 different lots of neoarsphenamin in dose of 0.200 gm. per kilogram, 79 per cent. of males and 84 per cent. of females survived.

Influence of Seasons.—Hunt[19] has observed that guinea-pigs are most resistant to acetonitril in the spring and summer months whereas mice were least resistant at those times. Roth[20] found that rats were more resistant to neoarsphenamin during the summer than during the winter months.

Influence of Marking and Handling Animals.—While rabbits and guinea-pigs are usually identified by metal tags or by registration of their color, mice and rats are generally marked by dyes on the tail or body or by clipping the fur. I have long used a saturated alcoholic extract of gentian-violet for this purpose with uniformly satisfactory results. In the Hygienic Laboratory a solution of picric acid has been employed, but after giving this method a trial, I became convinced that it increased the death rate among rats and mice employed for toxicity and trypanocidal tests with arsphenamin and neoarsphenamin. This appeared to be due to licking of the stains by the animals and possibly to some extent from absorption through the skin. Roth[21] has recently stated that he has been led to conclude that picric acid acted as a synergist to arsphenamin when mice were used as test animals, that is to say, increased the toxicity. For this reason, he advised the practice of clipping the animals over certain areas, but I have found marking with gentian-violet much less time consuming and quite satisfactory.

Lake states that the method employed in holding animals, which causes the least nervous irritation and physical exertion during the administration of the drug, has an important influence on lowering the toxicity. Since changing his method of holding rats by hand to my method of tying them to a board, shown in Fig. 1, the number of deaths occurring within a few minutes after the intravenous injection of arsphenamin has decreased to a marked extent. Of course, much less influence is exerted upon the results of trypanocidal tests, since the doses administered are smaller than employed in toxicity tests.

Influence of Route of Administration of Drugs.—As a general rule, the toxicity of drugs for the lower animals is determined by intravenous, intraperitoneal, intramuscular or subcutaneous injection. Occasionally, such tests are conducted by oral administration, subthecal or intrapleural injection, *but the route of administration has a profound influence upon toxicity and tolerance. It should be a general principle to administer a compound to the lower animals for toxicity and parasiticidal tests, by the same route or routes as are to be employed for administration to human subjects in the treatment of disease.* For example, arsphenamin is now administered almost entirely by intravenous injection and it is proper to test its toxicity and parasiticidal activities by the same route; sulpharsphenamin, however, is given by subcutaneous, intramuscular or intravenous injection and it is proper to determine its toxicity and parasiticidal (trypanocidal or spirochaeticidal) activities by intravenous and subcutaneous injection, since both values vary according to these routes of administration. To test the toxicity of a drug like arsphenamin by subcutaneous injection in mice or rats is a mistake; the compound should always be tested by the same route of administration as is used in its practical administration in order to elicit the considerable influence exerted by the blood and other factors upon toxicity. Route of administration is less important in relation to parasiticidal activities, but even here the influence is not inconsiderable or to be neglected.

In a general manner, intravenous injection produces a higher degree of toxicity than either subcutaneous or intramuscular injection or oral administration; an exception to this general rule, however, is noted with neoarsphenamin, which curiously, is not as well borne by subcutaneous injection as by intravenous and intraperitoneal injection. This was first described by Castelli[22] and subsequently confirmed by myself.[23]

Schamberg, Raiziss, Trist and I[24] have found the average relationship between intravenous and intramuscular injections of mercurial compounds to be about 4 to 1. For the mouse Castelli found arsphenamin 1.7 times less toxic by subcutaneous than by intravenous injection and neoarsphenamin about 10 times more toxic by subcutaneous than by intravenous injection. Schamberg, Raiziss and I[25] found arsphenamin about 3 times less toxic for the white rat by subcutaneous injection than by intravenous injection and neoarsphenamin about 0.6 to 0.7 times more toxic by subcutaneous than by intravenous injection. There was no constant or uniform relation among the highest tolerated doses of these different compounds for rats with the same route of administration. In very general terms, a compound is apt to be about 10 times more toxic by subthecal than by intravenous injection; 0.6 to 0.7 times more toxic by intrapleural, 1 to 4 times less toxic by intraperitoneal and 2 to 16 times less toxic by subcutaneous, than by intravenous injection.

Influence of Concentration of Solutions of Drugs and Rate of Injection upon Toxicity and Parasiticidal Tests.—These two factors are so closely related that they may be considered together. The rate of injection may be varied, while the concentration of the solution remains constant, or the concentration varied while the rate remains constant, so that the same amount of drug is mixed with the blood in the same length of time.

In the experiments of Schamberg, Raiziss and myself with solutions of arsphenamin varying in concentration from approximately 1 to 16 per cent. and slowly administered to rabbits by intravenous injection with a syringe, it was observed that increasing the concentration did not augment toxicity when *slow* injections were given. Subsequently I observed the same results with neoarsphenamin and sulpharsphenamin, but with all compounds, toxicity may be markedly increased by rapid injection and especially in the case of arsphenamin. For example, Lake has reported that of a series of rats injected intravenously with 0.060 gm. of arsphenamin per kilo in 1- or 2-per cent. solution, 75 per cent. died within four hours after rapid injection, while with the less rapid rate only 16.6 died. In all toxicity tests, therefore, these factors of rate of injection and concentration of solution require standardization and in the Hygienic Laboratory method for testing the toxicity of arsphenamin and neoarsphenamin, it is required that the former in 2-per cent. and the latter in 4-per cent. solution shall not be injected intravenously at a rate exceeding 0.5 c.c. per minute.

These experimental results are in keeping with clinical experience and especially in relation to the administration of arsphenamin. Neoarsphenamin and sulpharsphenamin may be injected in 5- to 10-per cent. solutions (0.6 to 0.9 gm. in 10 to 20 c.c.) and even in 30-per cent. solution (0.6 gm. in 2 c.c.) by means of a syringe without evidences of increased toxicity when given *slowly*, but the toxicity of arsphenamin is much more likely to be increased by such methods of administration, as discussed with more detail in Chapter LXII.

Period of Observation in Relation to Toxicity and Parasiticidal Tests in Animals.—Finally the period of time with which animals are kept under observation in toxicity and parasiticidal tests is one of considerable importance. Some drugs and chemical compounds show *early* toxic reactions, of which arsphenamin is a type; others show *delayed* toxic reactions, of which neoarsphenamin is a type, and when one reports upon the minimal lethal or maximum tolerated doses of any compound it is necessary to define the period of time arbitrarily adopted for determining the results. From the standpoint of the official Hygienic Laboratory rat test for the toxicity of the arsenicals, Roth has stated that it is apparent that when arsphenamin is examined one tests for its "acute toxicity" principally, since the rats die within forty-eight hours, for the most part within twenty-four hours. Rats, therefore, furnish no definite information as to the possible late effects of arsphenamin. However, rats show immediate symptoms after unusually toxic preparations of arsphenamin are given in the official dosage. These symptoms may probably be taken in part as a measure of the state of combination of the arsenical. Neoarsphenamin, on the other hand, causes slight or no immediate symptoms in rats on the official dosage, even when the drug has become insoluble; furthermore, the death is "subacute" or delayed, the animals dying, as a rule, after forty-eight hours. Mice die from "acute poisoning" after both arsphenamin and neoarsphenamin and, therefore, give a limited view of the behavior of neoarsphenamin in the organism. Guinea-pigs, like rats, usually die from "acute poisoning" after arsphenamin and from "delayed poisoning" after neoarsphenamin.

The results of my tests substantiate these observations. For example, of 201 different lots of arsphenamin tested by intravenous injection in dose of 0.100 gm. per kilo in 1042 rats according to the Hygienic Laboratory method, and 280 different lots of neoarsphenamin tested in dose of 0.200 gm. per kilo in 1585 rats, the death rates were as follows:

	Arsphenamin (Per Cent.)	Neoarsphenamin (Per Cent.)
At once	11.1	0.63
At end of 24 hours	15.4	3.2
At end of 48 hours	3.2	1.9
At end of 3 days	0.57	4.2
At end of 5–7 days	2.3	17.6
At end of 8–10 days	2.3	4.4
At end of 12–14 days	2.2	2.9
Surviving more than 14 days	62.2	64.0

In other words, about 38 per cent. of the rats injected with arsphenamin finally succumbed, but about 30 per cent. of these deaths occurred within forty-eight hours after injection and only 8 per cent. at subsequent periods. About 36 per cent. of the rats injected with neoarsphenamin succumbed, but only 5.7 per cent. in forty-eight hours, while 27.5 per cent. perished in seven days.

Somewhat similar results have been observed in a different set of tests. Of 181 lots of arsphenamin tested in doses varying from 0.100 to 0.200 gm. per kilo and of 278 lots of neoarsphenamin tested in doses varying from 0.200 to 0.400 gm. per kilo, the highest average doses producing death of the rats at varying intervals were as follows:

	Arsphenamin (Gm. per Kilo)	Neoarsphenamin (Gm. per Kilo)
At once	0.150	0.367
Survival 1 day	0.133	0.343
Survival 2 days	0.129	0.340
Survival 5 days	0.128	0.318
Survival 7 days	0.128	0.317
Survival 10 days	0.128	0.316
Survival 14 days	0.127	0.315

In other words, the highest tolerated dose of arsphenamin for rats remains quite constant after the first two days following intravenous injection, but with neoarsphenamin a decided drop occurs on or about the fifth day, following which the tolerance remains quite constant. Arsphenamin, therefore, produces acute or early toxic reactions, while neoarsphenamin produces subacute or late reactions; for these reasons, the Hygienic Laboratory permits reporting upon the maximum tolerated dose of arsphenamin at the end of forty-eight hours after injection, but requires a period of observation of seven days in the case of neoarsphenamin.

In trypanocidal tests by my method described in Chapter X, rats are kept under observation for at least two weeks because trypanosomiasis may develop as late as ten to fourteen days after inoculation when arsphenamin or some other trypanocidal agent is given in a dose just short of the completely sterilizing dose. In Voegtlin's method, however, the results are evaluated in two days after injection of the drug, but sometimes the blood of a rat showing no trypanosomes at this time will subsequently develop trypanosomiasis and perish. I believe, therefore, that in trypanocidal tests the animals should be kept under observation sufficiently long to express the minimal curative dose of the compound under study, that is to say, the smallest amount of drug per kilogram of weight capable of completely sterilizing the majority of a series of rats.

In spirocheticidal tests employing rabbits, a much longer period of observation is required, as described in Chapter XXI. Merely to determine the approximate amount of compound per kilogram of weight capable of removing spirochetes from scrotal or testicular lesions is insufficient; the neighboring lymphatic glands must be removed and inoculated into the testicles of additional rabbits to determine whether or not *complete* sterilization has been accomplished. Quite a number of compounds may cause spirochetes to disappear from the scrotal and testicular syphilitic lesions of rabbits, because these tend to heal spontaneously anyhow, but complete sterilization of the lymph-glands is another and very important matter, requiring at least four to six months of time for a complete test.

Factors Influencing the Dosage, Toxicity and Therapeutic Activity of Compounds in Man.—A considerable amount of the data to be secured by properly conducted toxicity tests with the lower animals is directly applicable to human beings. From the standpoint of chemotherapy, much of our data concerns arsphenamin and neoarsphenamin, but the principles established by experience with these is apparently applicable to other drugs and compounds administered after the same methods. Unquestionably

such factors as the diet, general health, individual susceptibility, pregnancy, route of administration, concentration of solutions, and rate of injection bear an even more important relation to the toxicity of drugs for human beings than they do for rats and other lower animals, as I shall discuss with considerable detail in subsequent chapters, but it is surprising how closely the data secured by animal tests corresponds to clinical experience. For these reasons, animal tests for the toxicity and parasiticidal activity of chemotherapeutic compounds are of great value when properly conducted and evaluated despite well recognized limitations and deficiencies.

I may, however, discuss at this time the matter of *dosage in relation to age and body weight.* In the first place children appear to stand better than adults such chemotherapeutic compounds as arsphenamin, neoarsphenamin, sulpharsphenamin, quinin, mercury and bismuth when based upon weight; as stated by Fowler[26] in relation to the solution of arsenic bearing his name, "I observed that children were less apt to suffer from the medicine than adults."

Age probably influences the toxicity and dosage of drugs by variations in blood volume, body surface and rate of protein metabolism. In the young the metabolic rate is greater than in that of adults, as has been indicated by Benedict[27] in his studies of the energy requirements of children. Furthermore, as shown by Benedict and Talbot,[28] there is some evidence that the active mass of the protoplasmic tissue determines the fundamental metabolism, and with advancing age this mass decreases in relation to the organism as a whole. Moreover, the blood volume decreases with advancing age, and as previously mentioned, Dreyer and Walker have shown that drug tolerance bears a close relation to this factor and body surface. These authors state that dosage in relation to the surface works out very simply as follows:

At 21 years	Full dose	At 3–4 years	$\frac{1}{3}$ dose
At 15 years	$\frac{3}{4}$ dose	At 1 year	$\frac{1}{4}$ dose
At 9–10 years	$\frac{1}{2}$ dose	In the early months	$\frac{1}{10}$ dose

To the best of my knowledge, age *per se* does not influence the parasiticidal activity of chemotherapeutic compounds. At least trypanosomiasis in a rat approximately three years old, which, according to Donaldson may be regarded as corresponding to a man ninety years old, is not more difficult to cure with arsphenamin or neoarsphenamin than a rat thirty-one days old which corresponds to a child of about two and one-half years. Testicular syphilis of old rabbits is likewise cured by these compounds as readily as similar lesions of the same duration in young rabbits. The duration of a disease profoundly influences parasiticidal effects, but the age of the patient probably does not and certainly not to the same degree as susceptibility or tolerance to toxic effects of drugs.

Technic of Toxicity Tests with the Lower Animals, with Special Reference to Arsphenamin and Neoarsphenamin.—It may be well to describe here with some detail the official Hygienic Laboratory method for determining the toxicity of arsphenamin, neoarsphenamin, sulpharsphenamin and allied compounds, because the method takes into consideration all of the factors influencing the results of toxicity tests in animals and serves as an excellent example of a technic applicable to the determination of the toxicity of other compounds. At least, I have found this method as herein described perfectly satisfactory for testing the mercurials, dyes, cinchonics and various organic and inorganic compounds of the heavy metals prepared in the course of chemotherapeutic investigations; some compounds may demand minor modifications in technic, but the method as a whole is an excellent one.

Plea for Standardized Methods.—The need for a standardized technic is evident when one considers the different methods employed for testing the toxicity of arsphenamin and neoarsphenamin in other countries as England, Canada, France and Japan, as recently reviewed by Roth.[29] For example, as there is no governmental regulation in Germany over the quality of drugs manufactured or sold in that country, the regulation of arsphenamin and neoarsphenamin is left entirely in the hands of the manufacturers. As a result of the various methods in use, a great deal of confusion exists in reference to the maximal tolerated doses of various compounds of chemotherapeutic interest and I wish here to enter a plea for the adoption of a standardized method for determining the toxicity of compounds for which I would propose the Hygienic Laboratory method of the U. S. Public Health and Marine Hospital Service, since it is suitable not only for testing the arsenicals, but for most other compounds as well.

Hygienic Laboratory Method for Testing the Toxicity of Arsphenamin.—The method employed in this country and largely built upon the studies of Schamberg, Raiziss and myself, Gies, Lake and Roth, is as follows:[30]

(1) The total arsenic content of the drug as obtained from the ampule shall not be below 30 *per cent.* nor above 32 *per cent.*, when determined according to Lehmann's method.

(2) The maximum tolerated dose shall not be less than 120 milligrams per kilo body weight for albino rats when tested as follows:

(3) Healthy white rats weighing from 100 to 150 grams are employed. Pregnant animals shall not be used. The diet may be of white bread, cracked corn, oats, cow's milk, and, in addition, twice weekly, fresh beef and cabbage or some other vegetable, but no food is given for at least 12 to 18 hours before the tests, though water should be supplied during this time.

(4) The drug shall be dissolved in freshly glass-distilled water and made into the alkaline solution by the addition of 0.9 c.c. $\frac{N}{1}$ sodium hydrate for each 0.1 gm. of the drug. The final concentration of the drug shall be in the proportion of 2 parts to 100. The drug shall be completely soluble in water in this proportion.

(5) Injection should be made into the saphenous vein by means of a burette or a syringe, accurately graduated to 0.01 c.c. When hemorrhage occurs it should be controlled mechanically.

(6) The rate of injection shall be at from 12 to 15 seconds for each 0.1 c.c. of the solution.

(7) An anesthetic is not required.

(8) For each toxicity test a series of not less than five rats shall be used, and at least 60 per cent. of the animals injected must survive at least forty-eight hours from the time of the injection, provided that, if the first test is made on five rats only and more than one die, the test must be repeated and the final result based on the total number of rats injected.

Hygienic Laboratory Method for Testing the Toxicity of Neoarsphenamin.—This is conducted in exactly the same manner with the following specifications:

(1) The total arsenic content of the drug as obtained from the ampule shall not be below 18 nor above 20 per cent. when determined according to Lehmann's method. The drug should be freely mobile in ampule and soluble in cold water (1 gm. in 10 c.c. of water in 5 minutes).

(2) The maximum tolerated dose shall not be less than 240 milligrams per kilo body weight for albino rats.

(3) The drug shall be dissolved in cold glass-distilled water. A preparation which is not readily soluble in cold distilled water should be discarded at once as a dangerous product. The final concentration of the solution shall be in the proportion of 4 parts per 100.

(4) For each toxicity test a series of not less than five rats shall be used, and at least 60 per cent. of the animals injected must survive at least seven days from the time of the injection, provided that if the first test is made on five rats only and more than one die the test must be repeated and the final result based on the total number of rats injected.

Hygienic Laboratory Methods for Testing the Toxicity of Sulpharsphenamin, Silver Arsphenamin, Silver Neoarsphenamin and Sodium Arsphenamin.—These are conducted in the same manner. Each must contain at least 20 per cent. of arsenic when determined according to Lehmann's method, with plus or minus 1 per cent. The solutions are prepared in the same manner as solutions of neoarsphenamin and the concentration of each drug shall be in the proportion of 4 parts in 100.

The maximum tolerated dose of *sulpharsphenamin* shall be not less than 300 mgm. per kilo bodyweight for albino rats; the dose for *silver arsphenamin* shall be not less than

140 mgm.; *silver neoarsphenamin* not less than 240 mgm. and *sodium arsphenamin* not less than 180 mgm. per kilo of body weight.

For each toxicity test a series of not less than five rats shall be used, and at least 60 per cent. of the animals injected must survive at least 7 days from the time of the injection, provided that if the first test is made on five rats only and more than one die the test must be repeated and the final result based on the total number of rats injected.

Apparatus for Intravenous Injection of Rats.—While rats may be injected at the uniform rate of 0.5 cc. in 60 seconds by means of a suitable syringe and needle as employed in the Hygienic Laboratory, I have found that these injections are very satisfactorily given in a saphenous vein exposed by a

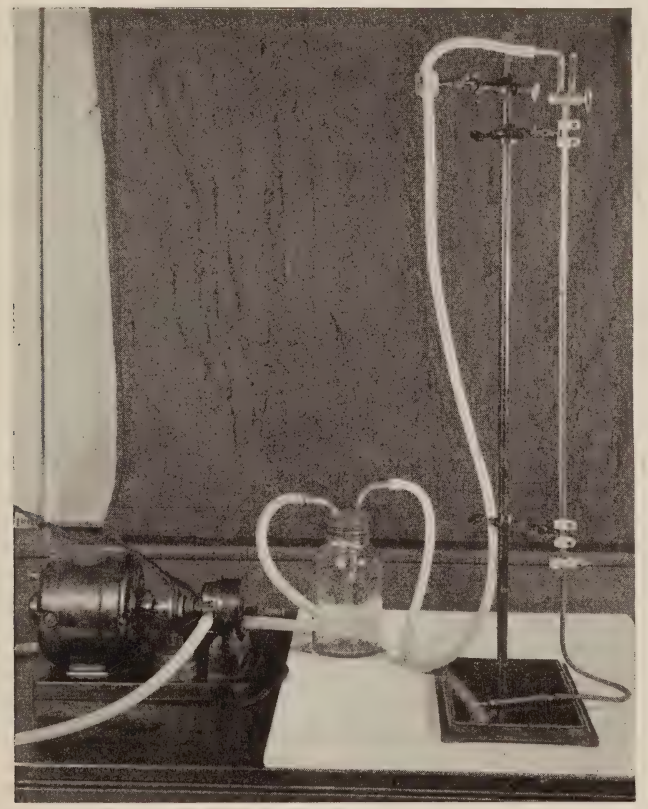

FIG. 1.—BURETTE FOR INTRAVENOUS ADMINISTRATIONS TO ANIMALS.

small incision by means of a gravity method employing the special apparatus designed by me after the apparatus used by Dr. Lake in the Hygienic Laboratory. This apparatus (Fig. 1) is composed of a 2 c.c. burette divided into 0.01 c.c. and fitted with a two-way cock at the upper end for filling by means of suction by vacuum and a water-tight cock at the lower end for stopping the injection. A long glass nozzle is attached to the burette fitted with a short piece of best grade rubber tubing carrying a window near the end, and a needle of No. 26 to No. 22 gauge.

Before injecting the solution the needle and rubber tubing are sterilized by boiling and the burette cleansed by copious flushing by means of the vacuum suction with sterile water followed by the solution to be injected, the water and solution of arsphenamin collecting in the bottle interposed

between the vacuum and the burette. When solutions are changed the apparatus is cleansed between each in the same manner.

After the animal is bound upon the operating board, the skin of the anterior surface of the thigh is cleansed with alcohol and a small incision made over the vein, which is rendered prominent by pressure made in the inguinal region by an assistant. The vein is grasped with fine forceps, due care being taken not to produce pain by grasping the nerve alongside of the vein, the needle is inserted and the cock gradually opened to regulate the flow while the time in seconds is called off by an assistant, until the dose to be given, previously marked off by the rider fastened to the burette, is injected.

With this apparatus it is possible to inject a given amount of solution very accurately and at a given rate of flow set down by the Hygienic Laboratory at 0.5 c.c. per sixty seconds; the amount of solution to be injected is calculated according to the dose to be given per 100 gm. of weight and the rate of injection can be nicely regulated by means of the stop cock and timed with a stop-clock. The apparatus is to be recommended for the intravenous injection of rats, guinea-pigs and rabbits, when a definite rate of flow is required in the conduct of toxicity tests with arsphenamin, tuberculin and various other drugs.

Technic of Intravenous Administration to Mice, Rats, Guinea-pigs and Rabbits.—In conclusion, it may be worth while to describe here the technic of intravenous administration to small laboratory animals; although quite easy for the experienced operator, the technic is usually rather difficult for the beginner and it is hoped that the somewhat detailed accounts given here may be of assistance. Roth[31] has described the following methods for the mouse, rat and guinea-pig:

White Mouse.—The lateral veins of the tail of the white mouse have been found best suited for intravenous administration purposes. The tail must be free from localized or generalized thickening of the epidermis so as to permit the ready entrance of a No. 23, B. & S. gauge needle. The use of a rather long needle, 1 inch in length, was found to be essential; it does not bend easily and therefore can be directed forward more readily than a smaller one.

A mouse weighing between 15 and 20 grams practically always possesses a soft, pliable tail which can be used without any preparation. When a mouse weighing over 20 grams is used, the lateral veins of the tail are usually covered with rather dense tissue, which precludes their use unless the tail is immersed for about a half minute in warm water (about 50°C.). This procedure both softens the skin and dilates the underlying vessels so that the vessels may be successfully used.

For holding the mouse, a small tin mailing tube attached to an iron stand is employed. One end of the metal mailing tube is fitted with a cork having at the circumference a V-shaped opening, which will admit the tail. The other end of the tube contains several small openings for the purpose of admitting air.

The mouse is grasped by the tail with the thumb and forefinger of the left hand and placed in the above-described metal mailing tube, and the cork is inserted so that the tail protrudes through the V-shaped opening. The tail is now straightened by gentle but firm traction and without twisting. The dorsal vein should then appear above, and each lateral to the left and right, respectively.

The syringe, usually a 1-cubic centimeter, all-glass, tuberculin type, graduated to $\frac{1}{100}$ of a cubic centimeter, is balanced between the first and middle fingers of the right hand, the hand resting on the little finger; the thumb is thus free to operate the piston of the syringe. With the syringe held

nearly parallel to the tail, the needle is pushed through the skin over one of the lateral veins (usually the left) and then anteriorly and downward into the vein. If an entrance into the vessel is not effected, either raising or lowering the point of the needle while advancing it further will usually succeed in locating the lumen of the vessel.

White Rat.—The official method for standardizing arsphenamin and allied compounds requires that either the right or left saphenous vein of the white rat shall be employed for the intravenous administration of these compounds. At the Hygienic Laboratory, however, the right vein is more frequently employed, and the procedure is essentially as follows: The animal is tied securely by the legs, back downward, to a flat operating board, by means of strings long enough to permit the hind legs to be lifted easily.

FIG. 2.—ROTH'S METHOD FOR INTRAVENOUS ADMINISTRATION OF THE WHITE MOUSE.

The operating board used in the Hygienic Laboratory is exceedingly simple, consisting of a piece of flat board having the dimensions 18 inches by 8 inches by 1 inch. At the end of the board to which the head is tied are two glass pegs about 1 inch long, set in at an angle in order to hold the string which is looped over the front legs of the animal. Nails in the other end of the board receive the strings which are looped to the hind legs. (Fig. 3.)

After shaving the hair over the skin area covering the left saphenous vein, the left foot is grasped between the third and middle fingers of the left hand, and an incision about one-fourth to one-half of an inch long is made about one-fourth of an inch to the left of and parallel to the vein. The skin is then rolled over to the right with the first finger of the left hand by drawing the skin on the back of the leg to the left. This will bring the vessel into view.

An assistant then makes compression to dilate the vessel. If a syringe is used, it is preferable to employ a 1-cubic centimeter, all glass, tuberculin type, graduated to $\frac{1}{100}$ of a cubic centimeter and fitted with a No. 26 B. & S. gauge needle, five-eights of an inch in length. The syringe is balanced between the first and middle fingers of the right hand, the hand resting on the little finger; the thumb is thus free to operate the piston of the syringe. The needle is then passed through the fascia and upper surfaces of the muscles, about one-eighth of an inch to the left of the vein and almost parallel to it. Advancing the needle slightly farther, the direction is changed so that the needle will enter the vein from the side. After the injection is made, the skin, which was pulled to the right to permit the vessel to come into view, is released,

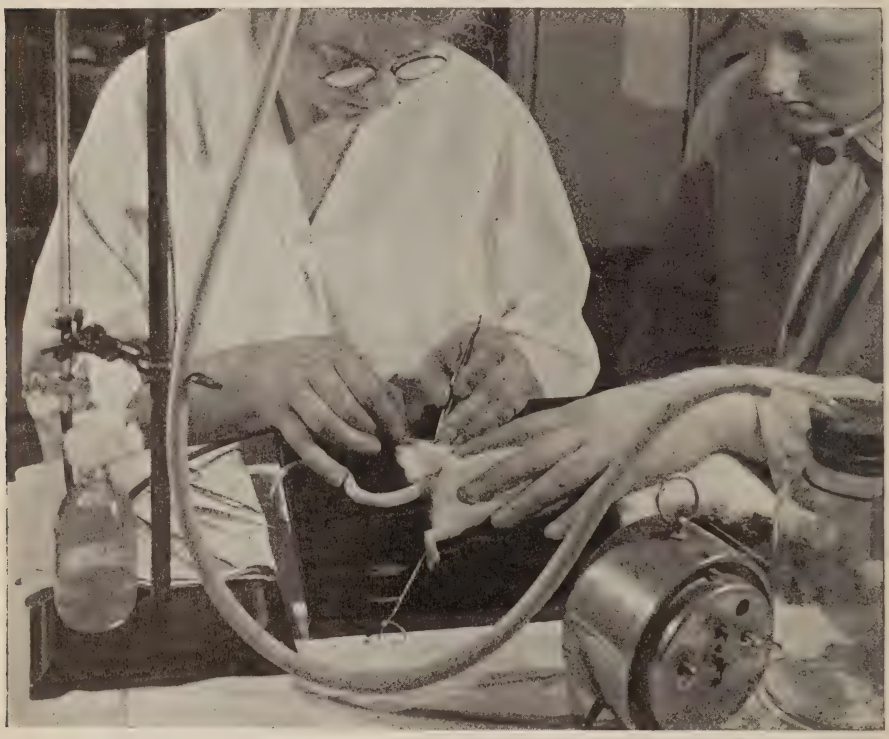

FIG. 3.—METHOD FOR INTRAVENOUS ADMINISTRATION OF THE WHITE RAT IN TOXICITY TESTS.

and this skin flap and the muscles act as effective mechanical checks to hemorrhage, which is quite profuse if the needle is inserted directly into the vein.

If a burette is employed and the injection made by gravity instead of by means of a syringe, a flexible rubber tube is attached to the burette, while the other end of the tube carries a glass tube which is drawn out and ground to fit a No. 23 B. & S. gauge needle 1 inch long. The glass tube is handled in the same way as the syringe, and the vessel is entered in the same manner as was described under the syringe method.

Guinea-pig.—The large superficial vein lying on the dorsal and inner aspect of the hind leg of the guinea pig is well adapted for intravenous administration. Occasionally, however, the vessel may run anteriorly. To use

the above-described vessel for intravenous administration, a special operating board is required. The board proper is similar to an ordinary animal board, except that the end to which the hind legs of the animal are tied has a U-shaped piece cut from it. The board is mounted near the center on an extension shaft which is fitted with two joints, the one at the end to which the board is attached being a ball-and-socket joint and the other an adjustable swivel joint. The shaft is screwed into a metal base which has sufficient weight to hold the board steady when placed in any position. A single operating board, however, may be used as shown in Fig. 4.

The procedure for making the injection is as follows: With the board properly placed in a horizontal position, the animal is tied to it securely, abdomen downward, by means of strings. The board is then placed in a vertical position and rotated on its vertical axis slightly so as to bring the dorsal aspect of the right hind leg into view. After clipping the hair from the leg and shaving it, the leg is lifted up slightly by the first or first and second

FIG. 4.—ROTH'S METHOD FOR INTRAVENOUS ADMINISTRATION OF THE GUINEA-PIG.

fingers and the vein dilated by suitable compression. The vessel can now usually be seen through the skin. A small incision, usually about one-fourth of an inch long, is made diagonally across the leg from the outer lower to the upper and inner aspect, but a trifle to the left of the vessel. The subcutaneous tissue is then pushed aside with a fine pointed forceps, thereby permitting the vessel to come into view.

The vessel is then entered directly or in the same manner as has been described for the rat—that is, by passing the needle of the tuberculin syringe through the fascia and muscles to the left of the vessel and then entering the vessel from the side. The vessel when dilated permits the ready entrance of a No. 23 B. & S. gauge needle. However, the needle usually employed is a No. 26 B. & S. gauge, five-eighths of an inch in length. The needle is always introduced well into the lumen of the vein. If entrance into the vessel is direct, subsequent hemorrhage may be controlled readily by pinching it with a small forceps.

Rabbit.—For intravenous injection of the rabbit the following method may be employed:

1. The posterior auricular vein along the outer margin of the ear is better adapted than a median vein for this purpose.

2. If a number of injections are to be made commence as near the tip of the ear as possible, as the vein may become occluded with thrombi, and subsequent inoculations may then be given nearer and nearer the root of the ear.

FIG. 5.—INTRAVENOUS INJECTION OF A RABBIT.

3. The animal should be held firmly, as the slightest movement may result in piercing the vein through and through and requiring reinsertion of the needle. This is accomplished satisfactorily by placing the rabbit upon the edge of the table and holding it firmly there by grasping the neck and front quarters, the assistant at the same time compressing the root of the ear with the thumb and forefinger.

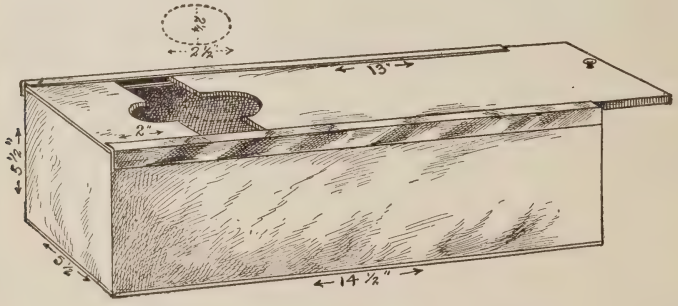

FIG. 6.—WOODEN BOX FOR HOLDING RABBITS FOR INTRAVENOUS INJECTION.

4. If the hair is long, clip it.

5. The ear is struck gently with the fingers and washed with alcohol and xylol; the friction will render the vein more conspicuous.

6. The ear is grasped at its tip and stretched toward the operator, or the vein may be steadied by rolling the ear gently over the left index-finger and holding it between the finger and thumb.

7. The inoculum should be free from solid particles and all the air excluded from the syringe. As a general rule, the amount injected should be as small

as possible, and the temperature of the inoculum be near that of the body. If the syringe is filled shortly after sterilization, when it has cooled enough to be comfortably hot to the touch, the heat will warm the injection fluid and not be hot enough to cause coagulation.

8. Hold the syringe as one would hold a pen, and thrust the point of the needle through the skin and the wall of the vein until it enters the lumen of the vein (Fig. 5).

The wooden box shown in Fig. 6 is very convenient for holding rabbits for intravenous injection or for bleeding from the ears.

9. Direct the assistant to release the pressure at the root of the ear, and slowly inject the inoculum. If the fluid is being forced into the subcutaneous tissue, which will be evident at once by the swelling which occurs, the injection must cease and another attempt be made.

10. The needle is quickly withdrawn, a small piece of cotton moistened with alcohol placed upon the puncture wound, and firm compression applied. Wash the ear thoroughly with alcohol and water to remove xylol, otherwise a low-grade inflammation will follow, which will render subsequent injections more difficult.

PART II

CHEMOTHERAPY OF BACTERIAL AND MYCOTIC DISEASES

CHAPTER III

PRINCIPLES OF THE CHEMOTHERAPY OF BACTERIAL DISEASES

While the foundations of our knowledge of the chemotherapy of disease have been mainly based upon studies in protozoan infections and especially trypanosomiasis and spirochetosis, and while great achievements have been realized in this new therapy and especially in the treatment of syphilis and frambesia tropica, yet the bacterial diseases offer an equally important field and not a little work has already been done with encouraging results. The conquest of tuberculosis, pneumonia, typhoid fever, streptococcus infections and numerous other systemic and localized bacterial infections by specific chemical disinfection of the tissues constitutes a field of endeavor worthy of the unremitting toil and interests of those engaged in chemotherapeutic investigation. Theoretically, at least, one may expect even greater success in the chemotherapy of bacterial than protozoan and metazoan diseases, since these simpler organisms are even less closely related to mammalian organisms than the latter, but experience has shown that actually this is not the case, probably because, in part at least, of the simpler nature and life processes of the bacteria which are therefore more difficult to cripple and destroy than the protozoa possessing more numerous and important life processes presenting more vital points and greater opportunities for chemical attack and destruction.

Historical.—When one realizes that attempts to disinfect a wound or cure a localized infection of the skin or a mucous membrane by the application of chemical bactericidal substances constitutes a form of chemotherapy, it is apparent that the chemical disinfection of bacterial infections has been practiced empirically for many years and indeed, long before the discovery of bacteria and the specific nature of bactericides. The frequency with which wine was employed, either alone or in combination with other substances for the irrigation of wounds in the Middle Ages is an example, since the alcohol doubtless exerted slight bactericidal effects; even the hot iron applied to wounds for hemostasis in the times antedating the introduction of ligatures may have had the extra but unsuspected virtue of disinfection and especially when the resulting sterile eschar and exudate was protected to some extent against secondary infection by the frequent application of the wine and balsamic mixtures possessing some slight degree of antiseptic activity.

Hand in hand with the discovery of pathogenic bacteria went the discovery of the bactericidal activity of phenol, mercuric chlorid and a host of other chemical agents. Naturally most of these early investigations were conducted by test-tube or *in vitro* methods employing pure cultures and when the high bactericidal activity of phenol, mercuric chlorid and other substances was discovered, great hopes were entertained and expressed by Koch and other pioneers regarding the development of methods for the successful disinfection of local and systemic diseases of the body by the use of chemical agents. But it was soon found that these substances were so toxic or organotropic for the body cells or so rapidly altered by the blood and other tissues that sufficient could not be administered for the specific disinfection of the body in systemic diseases, although some success and encour-

agement attended the disinfection of wounds and various localized infections. But in surgical practice aseptic technic soon commanded greater attention than antiseptic technic, and because of the local irritation and absorption of toxic amounts of phenol, mercurials, and other germicides applied to infected tissues, the chemical disinfection of wounds fell into disuse until revived with much success during the recent World War by Carrel and Dakin employing antiseptics of the chlorin group.

Probably the first serious attempt to develop the chemotherapy of a generalized or systemic bacterial infection was made by Morgenroth and Levy in 1911, working with a derivative of quinin called ethylhydrocuprein (optochin) and experimental pneumococcus infections of mice. This work yielded encouraging results and led to the trial of optochin in the treatment of lobar pneumonia by Moore and others. The results, however, have not been satisfactory because the curative dose approximates the toxic dose too closely and because of the influences exerted by the pathological changes in pneumonia about to be discussed, but nevertheless the synthesis of optochin gave great impetus to investigation in the chemotherapy of bacterial infections and was soon followed by that of Browning and his colleagues in England with studies of the acridin dyes and in this country by Churchman, with gentian-violet and other triphenylmethane dyes. Both of these investigators revived interest in the *in vitro* methods for studying the specific parasitropism of dyestuffs, and their work, especially that of Churchman, has resulted in the development of useful and encouraging methods for the treatment of local and systemic infections caused by the pyogenic organisms.

Morgenroth has consistently devoted his efforts to the development of what is designated as "chemotherapeutic antisepsis" and his work, already fruitful in the production of new acridin derivatives, developed by studies employing experimentally produced local and systemic streptococcus infections of mice, along with that of Carrel and Dakin, Churchman, Young, White and their associates, the latter producing mercurochrome for the treatment of local and systemic bacterial infections, has greatly advanced our knowledge of the chemotherapy of bacterial infections and produced drugs of practical value in the treatment of several. To these achievements I may add the efforts of Schamberg, Raiziss and myself with the synthesis of new mercurial compounds and especially of mercurophen for the treatment of localized infections.

Localized versus Generalized Bacterial Infections, in Relation to Chemotherapy.—It is readily apparent that the principles and mechanism of the chemotherapy of localized bacterial infections by the direct application of disinfectant substances are quite different from those concerned in generalized or systemic infections requiring the injection of the disinfectant into the blood or its absorption from the gastro-intestinal canal, muscles or subcutaneous tissues. From the standpoint of chemotherapy, a localized infection may be defined as one confined to a certain organ or tissue and reachable by direct or topical application of a chemical disinfectant. It may be a localized infection in the strict sense of being a tissue or organ directly or locally infected by an organism, as for example, the urethra by the gonococcus, but in relation to chemotherapy, it may also include a tissue or organ infected by way of the blood stream but yet treatable by the local application of a medicament to the infected parts; for example, a joint may be infected by a streptococcus conveyed in the blood from the apical abscess of a tooth but may be amenable to treatment by the local injection of a chemical disinfectant. Infections of the skin, the accessory sinuses of the upper respiratory tract, gums, conjunctivae, urethra, bladder, etc., are usually localized infections in the strict sense, but pleuritis, meningitis and infections of other serous cavities may be also classified as localized infections from the chemotherapeutic standpoint since they may be treated by direct local or topical application or injection of disinfectant substances even though the organisms are brought to the parts by systemic channels. On the other hand, certain infections of other organs as those of the iris, gall-bladder, perirenal tissues, etc., may be strictly localized but reachable therapeutically only by way of injection of medicaments directly into the blood or indirectly by absorption from the subcutaneous tissues, muscles or gastro-intestinal tract.

In other words, generalized or systemic infections are those in which organisms occur constantly or intermittently in the blood or lymph streams

with one or several localizations in the fixed tissues; usually they are treatable only by way of the lymph or blood streams by direct injection of medicaments into the blood or absorption from the subcutaneous tissues, muscles or gastro-intestinal tract. Localized infections are those in which the organisms occur in the infected parts as the result of a direct infection or by localization of organisms from the blood; according to accessibility of the part infected they may be treated by the topical application or systemic administration of drugs.

Principles of the Chemotherapy of Localized Bacterial Infections by Topical or Local Medication.—As previously stated, it is but natural that the treatment of wounds and superficial infections of the skin and mucous membranes by topical or local applications of chemical disinfectants should constitute the earliest empirical attempts in chemotherapy, even before the discovery of bacteria and their relation to infection. But with discoveries in bacteriology and of germicidal substances, the first practical application of knowledge regarding the latter was in the treatment of localized infections by topical applications. Upon first thought it does not appear that Lister's method of antisepsis by the carbolic acid spray was an application of chemotherapy, but in a strict sense this was true, since it constituted an attempt to selectively destroy organisms with a chemical agent without injury to the cells of the host. Owing, however, to the fact that the patient was sometimes poisoned locally or systematically by the phenol employed and since it was found that aseptic methods yielded better results than antiseptic methods in surgical operations, the method was discontinued.

But upon the discovery of the high bactericidal activity of the salts of mercury and other heavy metals as well as of alcohol and various other substances, interest in the treatment of infections of wounds and of local accessible tissues in general by the application of solutions of these substances was greatly renewed. It was soon observed, however, that the bactericidal activity of substances in the presence of blood and the tissue juices was much less than in the test-tube; likewise that the bactericides were unable to penetrate leukocytes and fixed tissue cells sufficiently well to reach organisms and that the agent may produce sufficient local irritation to preclude its use or result in the absorption of sufficient amounts to produce general poisoning. As a means for the treatment of infected wounds the topical application of bactericides was gradually discontinued, but never entirely abandoned, and during the World War was successfully revived by Carrel, Dakin and others. In other words, the practice involved has always been correct in principle; there was simply a failure to properly understand the technical and other factors guiding the selection of disinfecting agent and the manner of its application. Every time the surgeon disinfects the skin with iodin, picric acid or other chemical agent, he is practicing chemotherapy in a general way, since he seeks to reach and destroy organisms with a chemical agent employed in such strength as accomplishes this purpose without apparent injury to the patient. Every time an infected wound is irrigated with Dakin's or other germicidal solution by Carrel's or some other method, chemotherapy is being practiced in practically the same sense as the application of solutions of gentian-violet for the selective destruction of diphtheria and other Gram-positive organisms in wounds, as described by Churchman.

And the treatment of erysipelas and various other infections of the skin by applications of solutions of iodin, boric acid, mercurochrome and other agents, the application of solutions of boric acid, the silver salts, etc., to the conjunctival, the nasal mucosa and accessory sinuses, the urethra, etc., are likewise examples of chemotherapy in the empirical sense, long practiced

and generally useful since all represent attempts to destroy bacteria by the local or topical application of chemical agents employed in solutions of such strength as are bactericidal without demonstrable organotropic or toxic effects.

But what are the guiding principles of these very practical and important applications of the chemotherapy of localized infections? Does success in the sterilization of a wound, the skin or a mucous membrane depend entirely upon or necessarily bear an important relation to, the actual bactericidal activity of the chemical agent employed? Despite the fact of numerous mistakes and disappointments in the past on this score, the impression prevails that this is a consideration of first importance, but a close examination of the facts shows that it is not necessarily so and that other factors may be of equal or even greater importance. For example, a saturated solution of boric acid in water does not rank at all high in bactericidal activity, even under the best of conditions in the test-tube, and yet it constitutes one of the best and most successful topical applications for pyogenic infections of the skin and mucous membranes with which I am familiar, probably largely because of its osmotic absorption. The antiseptics of the chlorin group may be cited as additional chemical agents relatively feeble in bactericidal activity, but yet wonderfully efficient for the local disinfection of wounds when properly prepared and applied. And the list may be extended to include some of the organic silver salts, some of the acridin and triphenylmethane dyes, some of the essential oils, etc., possessing relatively feeble bactericidal activity as compared with the inorganic salts of mercury, but yet efficient disinfectors by topical application. From the standpoint of chemotherapy it would appear sufficient for a chemical agent to possess a moderate degree of bactericidal activity in the presence of blood, pus and other albuminous substances when applied in concentrations that are without local or systemic toxic effects for the cells of the host; in other words, mere superior bactericidal activity is not alone a criterion of success in the treatment of localized bacterial infections.

In addition, the disinfectant should possess the property of penetrating cells and tissues to reach organisms in the lymph spaces, lymphatic and vascular channels, as well as those protected by location in the protoplasm of leukocytes and other cells. If, in addition, the disinfectant has a dissolving effect upon dead cells and other organic matter (pus), an advantage is gained as shown, for example, in the effects of neutral sodium hypochlorite solution in the disinfection of infected wounds bathed in pus and necrotic tissues. Even the property of mechanical cleansing by floating pus from the depths to the surface is a matter of importance and the toxic qualities of the disinfectant for individual cells and especially phagocytes, as well as for complement and bactericidans in the blood and tissue fluids, are matters of primary interest and importance, as well as the question of local irritation with the production of pain and systemic poisoning from absorption.

Essential Properties of a Chemical Agent for the Chemotherapy of Localized Bacterial Infections by Topical Application.—If such are the main principles of the chemotherapy of localized infections of wounds, the skin, serous cavities (pleural, peritoneal, subarachanoidal, synovial, etc.) and such accessible mucous membranes as those of the urethra, bladder, upper respiratory tract, etc., it may be well to briefly summarize here our ideas of the essential properties to be possessed in whole or part by agents offered for the chemical disinfection of these tissues by direct or topical application:

1. *They should possess some degree of bactericidal and bacteriostatic activity* in the test tube and tissues, and especially in the presence of serum, blood, pus, etc. As previously

stated, these effects need not be extremely high and they may be selective, as for example, gentian-violet and other dyes of the triphenylmethane series for Gram-positive bacteria like staphylococci, streptococci, pneumococci, diphtheria bacilli, etc. While an extremely high bactericidal or bacteriostatic activity *in vitro* is not essential yet it is desirable, as such a compound is more apt to retain effective degrees of bacteriostatic activity *in vivo*. Furthermore, if the chemical agent possesses a high degree of selective bacteriostatic power, it may fail in the treatment of a mixed infection. For example, Bashford and his colleagues (1) found that in infected wounds treated with Dakin's solution, it was the cocci which disappeared last, while in wounds treated with flavin the commonest type of organism to outlive others on the wound surface was a Gram-negative bacillus. The same kind of result was obtained in Churchman's (2) efforts to sterilize amputation stumps with gentian-violet. It was comparatively simple to get rid of the Gram-positive *Bacillus diphtheriae*, but very difficult to abolish the Gram negative *Bacillus coli*.

2. *In addition they should possess the property of destroying toxins and especially the toxins of the tetanus and other anerobic bacilli of infected wounds;* in this connection it may be stated that the oxidizing disinfectants, as those of the chlorin group, are believed to have this property.

3. *They should not be precipitated or their bactericidal properties neutralized by the proteins or salts of the polybasic acids of the body fluids and tissues* with which they come in contact, as by pus and necrotic tissues in wounds or serous cavities, by urine in the pelvis of the kidney or bladder, etc.

4. *They should possess the property of penetrating cells and tissues and especially phagocytic leukocytes and other cells in which living bacteria may be lurking.* This is one of the most important principles of all and especially in the treatment of chronic infections of mucous membranes in which the bacteria are almost sure to have taken up a position of grest strategic strength in the depths of glands and cells.

5. *They should be free of local organotropic or toxic effects for the fixed tissues*, that is, free or almost so, of irritating and inflammatory properties; on the contrary they should be of a soothing or bland nature and preferably possess some degree of analgesic effect.

6. *They should not be excessively toxic for the body as a whole in case considerable amounts are absorbed.* This is especially important in the irrigation of wounds and much less so in infections of the skin and mucous membranes, the whole subject bearing a direct relation to the question of absorption.

7. *They should exert a chemotactic effect*, that is, attract leukocytes about the focus of infection and thereby aid in the walling off of the involved area and possibly aid phagocytosis and the elaboration of cellular proteolytic and lipolytic enzymes. At least, they should not repel or destroy leukocytes and thereby favor the extension of the infection.

8. *They should not destroy or paralyze the immunological substances like complement, bacteriolysins and opsonins (bacteriotropins)* concerned in the destruction of organisms.

9. *They should be rapid in bacteriostatic and bactericidal activity.* This is especially important in the treatment of such infected surfaces as the urethra, conjunctiva, etc., where the contact of disinfectant is extremely brief. Indeed, this largely accounts for failure in practice and it is commonly observed that clinical results are very much better when the disinfectant is retained for some time, as, for example, in the case of instillations into the urinary bladder or when it is frequently applied, as in the Carrel method of irrigation of wounds. But whenever the conditions are such that prolonged contact is not possible, rapid penetration and rapid bactericidal effects become of increasing practical importance.

10. *They should possess some degree of dynamogenic activity*, that is, the property of stimulating the fixed tissues to proliferative activity as a further aid in the walling off of lesions followed by cutting off oxygen and blood supply to the organisms and thereby allowing their own acid and waste products to check their growth and eventually destroy them.

Methods of Topical Treatment of Localized Infections in Relation to Chemotherapy.—But a compound possessing all or the majority of these essential and desirable properties may yet fail to prove useful in the treatment of localized bacterial infections because it may not be possible to apply it correctly. Indeed, I believe that the essential reason for the skepticism of surgeons regarding the practical value of topical applications of chemical disinfectants in the treatment of infected wounds, serous cavities, sinuses, etc., is due largely to the difficulties or impossibility of correct application. Merely to apply the disinfectant on gauze is usually insufficient as this may only protect against secondary infection without appreciably influencing the existing infection. As so clearly shown by Carrel and his colleagues with

the chlorin group of antiseptics in the treatment of infected wounds, it is essential to bring the disinfectant solution into frequent and intimate contact with the infected tissues along with the surgical removal of necrotic tissues when possible and advisable and always the establishment of the best possible drainage. Furthermore, these ends should be attained with the least meddling and disturbance in order to permit granulation and healing to proceed; for these reasons Carrel has contributed his valuable method of irrigation with rubber tubes laid in the wound as a substitute for frequent syringings and packings.

The method of application, therefore, is of considerable importance; indeed, I believe it decidedly outranks in importance the choice of antiseptic solution itself provided the latter approaches in blandness simple physiological saline or Locke's solutions with a reasonable degree of bactericidal activity, and the essential principles involved may be summarized somewhat as follows:

1. Free drainage is of the utmost importance and should be provided for by surgical means if necessary. This will facilitate better access of the disinfectant to the infected tissues, reduce dilution of the disinfectant to a minimum, reduce the degree of absorption of toxic substances from bacteria and necrotic exudates and tissues and minimize the danger of spreading the infection by over-distention of the tissues when a cavity is present.

2. In infected wounds, bits of necrotic tissue should be removed surgically, if possible, without too much danger of spreading infection, in order to remove or prevent the formation of pockets constituting good breeding places for bacteria, particularly the anaërobes, and which may be a constant source of re-infection of the tissues.

3. The disinfectant solution should be frequently applied. In the Carrel method employing a chlorin antiseptic this may be as often as every two hours. To apply the disinfectant once a day at the time of dressing the parts is usually insufficient and merely a cleansing process, because of the very brief contact between disinfectant and the tissues. Even though the lesion may not demand a complete set of Carrel tubes, the proper placement of a single tube of the right kind with the frequent injection of disinfectant with a syringe may serve the purpose without disturbing the dressings. It is largely because frequent applications are not usually possible in the treatment of chronic infections of the nasal accessory sinuses, that their treatment is so generally unsatisfactory; on the other hand, in acute and chronic conjunctivitis the method of frequent applications is usually practiced and for this reason excellent results are obtained by the instillation of medicaments possessing but feeble bactericidal activity but serving a very useful purpose by merely cleansing the infected tissues with frequent removal of pus, bacteria and toxins.

The correct principles, therefore, are free drainage and frequent applications of a disinfectant solution possessing the essential properties described above. Under these conditions bacteria and their toxins, as well as the toxic substances of protein digestion of the necrotic tissues and exudates, are being constantly removed and their absorption reduced to a minimum; in addition enormous numbers of bacteria may be killed, or at least their proliferation prevented, if the disinfectant fails as a bactericide but functions as an antiseptic or bacteriostatic agent. Such management permits phagocytosis to proceed by removing the aggressin-like bacterial toxins which tend to prevent this important curative process; the extension of bacteria along the lymphatics is discouraged; the danger of development of bacteremia (septicemia) is greatly minimized and the degree of sapremia from absorption of toxic exudates is reduced.

4. Finally, the disinfectant should be introduced with practically no pressure in order to avoid over distention of the tissues, which may disseminate the infection. Gentleness and the minimum of handling are of primary importance.

Varieties of Localized Infections in Relation to Chemotherapy.—But, of course, not all localized bacterial infections demand disinfectant treatment. Judgment must be exercised according to the kind of organism present and the duration and extent of the lesion. Ordinary acute staphylococcus abscesses, for example, usually do best with simple incision for adequate drainage and much handling, squeezing and syringing are to be avoided. As a general rule, when the incisions of a localized lesion are only large enough for drainage, no attempt should be made to disinfect because

of the danger of blocking drainage by additional tubes, but in large lesions, as infected wounds, widely incised staphylococcus and streptococcus abscesses, streptococcus infections of the uterus, etc., where provision may be made for both drainage and irrigation, I believe that disinfection at short intervals is indicated and especially in streptococcus infections.

It is true that disinfectant solutions may not reach or influence those bacteria already deep situated in the tissues and especially in the lymphatics, but the proper kind of disinfectant solution along with drainage may tend to reverse osmosis and thereby reduce the degree of absorption of bacteria and toxins and at least greatly reduce their production which may be a factor of no little value in streptococcus and pneumococcus infections. Furthermore, some localized bacterial lesions cannot be subjected to frequent disinfection because of anatomical difficulties. For example, in pneumococcus and streptococcus cerebrospinal meningitis adequate drainage and disinfection are not ordinarily provided for and I am convinced that daily or twice daily spinal drainage with the injection of a serum or chemical disinfectant in the lumbar region are insufficient. It is imperative for surgeons to perfect a method for frequent drainage if anything worth while is to be accomplished in these dreaded and highly fatal infections; if, in addition, ways and means are provided for cleansing and disinfecting the subarachanoid space at frequent intervals, the chances of success will be much greater. But the problem of the disinfectant is practically solved; it awaits the development of better surgical procedures for its introduction and adequate drainage. The ear and accessory sinuses of the nose likewise present difficulties and for this reason oto-rhinologists have not found disinfectant solutions of particular value in treatment; but I believe this is largely due to the fact that the disinfectant cannot be kept in contact with the infected tissues for sufficient periods of time and indeed, may not reach some deeper parts at all, although it is possible that gaseous disinfectants of the chlorin type may be employed with greater success and especially if means are provided for the patient to apply these at frequent intervals.

But in the treatment of chronic empyema, chronic suppurative arthritis, chronic suppurating sinuses, osteomylitis, endometritis, etc., the possible advantages from well directed attempts at disinfection at short intervals should not be overlooked or minimized and I believe these localized infections constitute a proper field for coöperation between surgeon and chemotherapeutist; for this reason I shall be bold enough to offer advice in regards to local disinfection when taking up for consideration the practical application of chemotherapy in the treatment of localized and systemic bacterial infection in Chapter VIII.

Chemotherapy of Localized Bacterial Infections by the Systemic Administration of Medicaments.—Is it possible to disinfect a strictly localized bacterial infection by the administration of a compound by intravenous or subcutaneous injection or oral administration? This is a very broad and important question involving the present state of the chemotherapy of bacterial diseases in general since tuberculosis, bacterial endocarditis, pneumonia, puerperal sepsis, etc., may be localized infections in just the same sense as an abscess at the root of a tooth, a sinusitis, a staphylococcus or streptococcus cellulitis and lymph-adenitis, etc.; it involves primarily the question of penetration of chemical agents from the blood into the tissues of bacterial infection, which will be shortly discussed with detail, but here it may be stated that a general answer cannot be given, since it would appear that the matter of penetration varies according to the infection and the kind of compound administered. For example, it is doubtful if we have available

at present a chemotherapeutic agent capable of penetrating tubercles although some of the dyes may do so; on the other hand, clinical reports indicate that gentian-violet and mercurochrome are apparently able to penetrate localized infections caused by *B. coli*, straphylococci and streptococci although Hirschfelder, Malmgren and Creavy[3] have recently reported that while mercurochrome and acriflavin may penetrate gradually from the blood into the edema fluid produced by paraphenylendiamin, this does not occur with doses proportional to those employed clinically and that neither these compounds nor gentian-violet in such amounts rendered the edema fluid bactericidal or bacteriostatic. I have repeatedly observed that the intravenous injection of mercurochrome, gentian-violet and acriflavin failed to sterilize the pus of abscesses at the roots of teeth showing hemolytic and non-hemolytic streptococci in cultures; also that pneumococci in the pus of infections of the nasal accessory sinuses were apparently untouched, but mercurochrome in my experience has apparently penetrated acute staphylococcus and streptococcus lesions of the subcutaneous tissues, lymph-glands and endometrium with curative effects. As previously stated, I shall shortly discuss this subject with more detail, but here it may be stated that in severe acute localized bacterial infections it may be possible to re-enforce disinfection by local or topical application of disinfecting agents by the systemic administration of a medicament and especially by the administration of mercurochrome.

Related to this subject of specific chemotherapeusis of local bacterial infections by the topical or local application or systemic administration of a disinfectant agent, is the possibility of treating infections of the organs of the urinary, biliary, gastro-intestinal, respiratory and cutaneous systems by the administration of compounds largely eliminated in these tracts. Hexamethylamin, for example, apparently owes a part of its beneficial effects in the treatment of infections of the genito-urinary organs to the elimination of small fractions of formaldehyd liberated in acid urine, although it is doubtful if sufficient formaldehyd is liberated in other tissues as in the bile, milk, saliva, cerebrospinal fluid, etc., to produce beneficial results and hexamethylamin itself is practically free of bactericidal effects in the amounts ordinarily eliminated unchanged. Recently it has been shown that mercurochrome and hexy-resorcinol administered by ingestion or intravenous injection may be eliminated in the urine in sufficient amounts to render it bactericidal and the same may be true to a lesser extent of other mercurial compounds. It is well known that arsenic is largely eliminated in the bile, but unfortunately the bactericidal activities are so feeble that curative effects in bacterial infections of the liver, gall-bladder and ducts are not apparent. It is not improbable, however, that mercurial compounds eliminated in the bile may reach bacteriostatic concentrations and even reduce to some extent the bacterial flora of the small intestines. The beneficial effects of creosote, guaiacol and their derivatives in bronchitis are apparently due in part to their elimination in the bronchial secretions, but I do not know of any drug eliminated by the skin exerting curative activity in bacterial infections of this organ.

But the principle is well established and worthy of much more attention than has been heretofore given this subject. This is especially true of bacterial infections of the genito-urinary organs and biliary passages. It is probable, however, that compounds eliminated in the urine and bile may be so profoundly altered that bactericidal effects are lost; this is apparently true of the organic trivalent arsenicals like arsphenamin and neoarsphenamin, which are largely eliminated in the bile as inert pentavalent compounds and

half- or pseudo-complex compounds of mercury may become dissociated and combine with proteins and thereby loose greatly in bactericidal effects, etc. Unfortunately, the converse of this is apparently of infrequent occurrence; that is, relatively inert compounds do not acquire bactericidal effects during elimination except in the case of hexamethylamin when traces of formaldehyd are liberated in an acid medium. But it may be that similar effects are more common than we now suppose and thereby explain such beneficial results as those observed, for example, with creosote, guaiacol and their derivatives in bronchial infections, the salicylates in acute rheumatic fever, etc., which possess but feeble bactericidal effects *in vitro*.

In a broad and general manner, it may be stated that the secretions of organs are much less likely to eliminate drugs to a sufficient extent to secure curative effects in bacterial infections than the excretions. For example, we do not possess at present a bactericidal drug capable of passing the choroid plexus in meningitis; hexamethylamin may pass, but bactericidal amounts of formaldehyd are not liberated. But in recent experiments I have found that traces of ethylhydrocuprein administered by intravenous injection and even by ingestion to dogs and rabbits, may occur in traces in the cerebrospinal fluid in pneumococcus meningitis and I have likewise detected mercury in the fluid in experimental streptococcus meningitis following the intravenous injection of mercurochrome. In other words, while drugs may not find their way into the subarachnoid space under normal conditions, yet such may occur as the result of acute inflammatory changes of the meninges and choroid plexus.

Examples of these kinds could be further multiplied, but I hope my purpose is fulfilled by those given, which is to draw more attention to the possibilities of influencing infections through the action of disinfectants eliminated in the excretions and secretions of the body modified by disease. In this connection it is hardly necessary to emphasize that studies upon elimination by *normal* organs are apt to be insufficient; for example, when we approach the matter of elimination of disinfectants in the cerebrospinal fluid for the treatment of meningitis, we should experimentally produce a meningitis in the animal and the same is true in studies of elimination by bile. There is, in other words, likely to be considerable difference between elimination by a normal organ and elimination by a diseased organ and our experimental conditions should approximate those of the disease we seek to influence or cure.

Principles of the Chemotherapy of Bacterial Infections by Systemic Medication.—By systemic medication I mean the administration of medicinal agents by ingestion or injection (subcutaneous, intramuscular, intravenous, etc.) and their subsequent distribution by the blood. This introduces new problems concerning the fate of the compound before it has had an opportunity for attacking the organisms and the opportunities and chances for effective disinfection are greatly reduced in comparison with disinfection by direct application.

In the first place, the compound is immediately diluted to a high degree in the blood and other body fluids and this alone may suffice for reducing it below a bactericidal concentration. Furthermore, elimination is likely to begin almost immediately and this, along with the rapid absorption or removal of the compound from the blood by physical or chemical union with the fixed tissue cells or its rapid conversion into an inert compound, may result in a still greater reduction in bactericidal activity and effectiveness. It is true that none of these unfavorable influences may be sufficiently prompt or powerful to prevent the compound from disinfecting the blood, but they are

apt to be very real obstacles in the path of a disinfectant between the site of its administration and the organisms in the fixed tissues protected by edematous fluid, necrotic cells and vascular occlusions. For these reasons chemotherapy may be much more effective in the disinfection of the blood and in keeping the blood in a sterile condition than in the disinfection of a bacterial infection localized in some tissue or organ and, indeed, my clinical and laboratory experience indicates that such may be true in streptococcus and pneumococcus infections.

On the other hand, a compound may undergo an increase rather than a decrease of parasitropic activity in the blood. It would appear that this occurs in the case of arsphenamin and other trivalent arsenicals by the formation of the trivalent "oxids" of which arsenoxid is the type, and apparently some analogous change must occur in the case of the salicylates to account for their curative effects in acute rheumatic fever. Indeed, I am inclined to believe that progress in chemotherapy has been hampered somewhat by placing too much emphasis upon bactericidal effects *in vitro* and discarding new compounds on the basis of low bactericidal activity without giving them a trial *in vivo* for the possible chance of their being more parasitropic under such conditions than we may naturally expect. Mercurochrome for example, would never greatly impress one as a compound of promise in the treatment of a bacterial infection because of its relatively feeble bactericidal activity *in vitro* in comparison with gentian-violet, but yet, *in vivo*, mercurochrome has proved more effective in my experience than the latter largely because gentian-violet is rapidly reduced to an inert compound while mercurochrome is more stable even though it does not appear to be converted into a new or more active substance.

But the disadvantages of rapid dilution, rapid elimination and rapid fixation by the tissue cells are to be reckoned with in any event and demand that they be taken into consideration in our dosage and method of administration in order to maintain an effective concentration of the drug in the blood for suitable periods of time.

In addition to these factors involving the metabolization of the compound, it must be of sufficiently low toxicity or organotropism to permit of administration of adequate amounts without undue risks of temporary or permanent damage to physiological important cells and organs and it must possess the property of penetrating new bacterial tissues and exudates in an active state for the purpose of effecting their disinfection. The latter is indeed a consideration of first importance in the chemotherapy of all bacterial infections other than of bacteremias or septicemias. It would appear to be the main stumbling block in the development of an effective chemotherapy of tuberculosis, pneumonia, actinomycosis and such infections characterized by profound pathological tissue changes. The laws governing this important subject of capillary permeability and the penetration of lesions by chemical agents have not been worked out although it is a problem of first rate importance. It may be that the determining factor is a matter of the chemistry of the organisms as influencing affinity for bactericidal compounds, but it is more likely to be one of physics involving the simple laws of diffusion of crystalloids and colloids as well as molecular size or magnitude. The pathology of a disease may, therefore, profoundly influence its chemotherapy and largely by its modifying influence upon capillary permeability and tissue penetrability, as I shall shortly discuss with more detail.

Essential Properties of a Chemical Agent for the Chemotherapy of Bacterial Diseases by Systemic Administration.—With these considerations in mind we may now briefly summarize the essential properties of a chemical

agent in relation to the chemotherapy of bacterial diseases, when administered by ingestion or injection and presumably distributed by the blood and other body fluids:

1. It must be of sufficiently low toxicity for the body cells to permit of the safe administration of adequate amounts without delayed toxic effects or the production of too violent immediate reactions by incompatibility with the blood.

2. It must be sufficiently toxic for the bacteria to exert bactericidal and bacteriostatic effects. For this purpose it must be either sufficiently high in bactericidal activity to be effective in the blood despite high dilution or be a compound convertible in the blood and tissues into a new compound of higher parasitropic activity.

3. It must not enter too rapidly into physical or chemical union with the constituents of the blood or fixed tissues with the production of inert compounds.

4. From the standpoint of the treatment of tuberculosis and other bacterial infections characterized by the production of pathological exudates and tissues, it must possess the property of penetration sufficient for disinfective purposes by conforming to the physical laws of diffusion or by possessing a chemical affinity for the proteins or other constituents of the organisms according to Ehrlich's conception of parasitropic activity. This, however, is not required for the disinfection of the blood and lymph although an affinity between compound and organism must exist.

5. The compound should not depress immunological processes and especially phagocytosis. On the other hand, it should produce leucocytosis and enhance phagocytosis in both the blood and fixed tissues.

6. In addition to these desirable qualities, the curative activity of a chemotherapeutic agent or drug may be enhanced if it possess some degree of dynamogenic and chemotactic activity, which is the property of exciting hyperemia about lesions with serous and cellular exudation and promoting the proliferation of connective tissue which tends to wall of chronic lesions and gradually aid in their disinfection by cutting off oxygen and food supply and allowing the acids and waste products of bacteria and the products of caseation and liquifying necrosis to check and eventually destroy the organisms.

Pathology of Bacterial Diseases in Relation to Chemotherapy.—As would be expected better results are observed in the chemotherapy of acute than of chronic bacterial infections. Probably best results of all are secured in the disinfection of the blood in cases of bacteremia (septicemia). This is true because we have a few drugs like ethylhydrocuprein hydrochlorid, mercurochrome and gentian-violet which may be given in sufficient amounts to temporarily raise the bactericidal titer of the blood for effective sterilization although it may become re-infected a few hours later by organisms from localized lesions escaping disinfection.

But organisms in the fixed tissues can only be reached and destroyed when sufficient amounts of the compound in an active bactericidal state leaves the blood and permeates the lesion. This in turn involves the questions of rapidity of elimination, production of inert combination compounds, the physical laws of diffusion, capillary permeability, etc., discussed above; it also involves the degree and kind of pathological tissue changes which may be present and constituting the theme of the present discussion.

In acute bacterial infections the hyperemia is undoubtedly a favoring factor for bringing the bactericide to the sites of infection and during the processes of acute cellular and serous exudation a part of it may be swept along into the inflammatory exudates even though the compound itself does not possess those physical characteristics which facilitates its passage through the walls of normal vessels. Permeability is of fundamental importance, but in acute inflammatory lesions it may not be as important as in chronic lesions because of the opportunities of the compound being carried along mechanically in the former into the infected tissues by the processes just mentioned. We may expect, therefore, better results in acute than in chronic infections. But even when compounds like mercurochrome, acriflavin, gentian-violet, optochin, etc., leave the capillaries, their diffusion may be hindered by the physical characteristics of the edematous fluid and

pus as well as by the leukocytes and other cells containing many of the organisms. The problems, therefore, are many and difficult and particularly good results may not be obtained until we learn more about the laws governing permeability and diffusion under these circumstances and until we succeed in evolving compounds which will accumulate in the lesions to reach bactericidal concentrations, which I believe occurs with mercury in the treatment of syphilis and explains its peculiar efficacy in this disease.

In chronic bacterial diseases the lesions may be quite avascular, as in the case of tuberculosis; furthermore, many of the blood-vessels are apt to be sclerosed which may amount to occlusion of the smaller vessels. Serous and cellular exudation are reduced to a minimum and we have therefore a set of circumstances very unfavorable for chemotherapy and especially if our compounds possess but feeble permeability for capillaries at best and a low diffusibility in the products of caseation and liquifying necrosis.

Needless to state the pathological lesions produced by bacterial infections may also influence the organotropism or toxicity of compounds for the body cells. It is commonly observed that the tolerance of infected animals for a drug is appreciably less than in normal animals and I believe the same is true of human beings. The bacterial toxins and exudates are always likely to produce albuminous degeneration of the kidneys, heart and other organs which may proceed to more advanced lesions and interfere with elimination to such an extent as may increase the chances for toxic effects and especially in the case of chronic diseases. On the other hand, however, just the opposite may occur during the acute stages; for example, the patient with croupous pneumonia has, I believe, a higher tolerance for optochin and quinin compounds in general than normal human beings. This is analogous to the increased tolerance of syphilitics for mercury and of malarial infected individuals for quinin. In other words, the toxins of the disease or some other agencies may have a de-toxifying effect upon the drug administered.

Even in localized bacterial infections pathological tissue changes may profoundly influence the results of chemotherapy by topical or direct application. In acute lesions the organisms are more superficial and, therefore, of easier access than in chronic lesions; in the latter, the bacteria are apt to be in the depths of glands and even in the submucous tissues protected against destruction not only by this location but likewise by the production of inflammatory exudates and fibrous tissue. It is for these reasons, therefore, that compounds possessing penetrability in greatest degree like the stains and dyes, are most likely to be successful. Indeed, I believe we may go so far as to state that compounds lacking in this quality can never prove very useful in the treatment of chronic infections by direct application, as they come in contact and destroy only those organisms swept out to the surface by the secretions and excretions and many of which are already dead, without being able to penetrate and reach the real offenders deeply and safely lodged in the tissues.

Dosage and Route of Administration in Relation to Bacterial Chemotherapy.—Naturally enough, these considerations also bear an important relation to our methods of administering compounds in the chemotherapy of bacterial diseases and especially by systemic routes of administration. In the treatment of the septicemias, it would appear advisable to give large doses by intravenous injection in order to raise the bactericidal activity of the blood to a high level even if for but a short period of time, as one to three hours. Small, frequently repeated doses may fail to accomplish disinfection if elimination and metabolization prevent the compound from reaching a bactericidal concentration in the blood under these circumstances, although

this method of administration may greatly aid in keeping the blood sterile, as during croupous pneumonia, streptococcus cellulitis, anthrax, etc.

But how may we encourage the penetration of chemotherapeutic drugs into the fixed tissues infected with bacteria? Experiments and clinical experience indicate that this is likewise probably best accomplished by large single doses although it may be shown in the future that it can be better accomplished by smaller and more frequent doses and especially if compounds are discovered possessing a higher affinity for bacterial tissues than is now apparently the case with the drugs so far produced. In other words, I believe that the correct method of administration with the compounds now available is to hit hard and quickly over a short period of time in the treatment of the acute bacterial diseases and especially the septicemias. With mercurochrome this usually means a dose of about 0.005 gm. per kilo of weight or approximately 23 c.c. of a 1-per cent. solution for an adult weighing from 130 to 140 pounds; but instead of giving all of this in one dose, it may be possible to secure results by giving 10 c.c. daily for three or four days in succession and I have had a few cases in which this plan has apparently been efficacious although in general terms better results have followed the slow injection of 25 to 30 c.c. followed by the acute reaction of chill, fever and diarrhea. This would appear to be the best means for disinfecting the blood and for encouraging penetration of the fixed tissues and exudates. Exactly the same principle pertains to the treatment of the acute bacterial diseases with immune serums, since better results appear to follow large doses at short intervals by intravenous injection over a period of a few days than small doses over a long period.

But in chronic bacterial diseases in which the blood is sterile the chief purpose is to encourage penetration of the lesions with the medicament. At present we do not appear to have a compound at our disposal which possesses an affinity for the bacterial tissue and a tendency to accumulate there in a manner similar, for example, to the accumulative effects of small doses of mercury over a long period of time in the treatment of syphilis, unless it be the salicylates in acute rheumatic fever. Experiments and clinical experience indicate that best penetration is probably secured by bringing about the highest concentrations in the blood, even if but for a few hours at a time, so that we are compelled to adopt the practice of large doses in a short interval as preferable to small doses over a long interval. Unfortunately this practice is not without danger, since the amounts of optochin, mercurochrome, gentian-violet, acriflavin and other drugs employed at present in bacterial chemotherapy required to produce curative effects may be so near their toxic doses that repeated large doses at close intervals may be dangerous and requiring considerable clinical experience and judgment in the selection of drugs, their doses and route of administration.

Influence of Chemotherapy upon the Immunological Changes of Bacterial Diseases.—Until we succeed in producing far more satisfactory chemotherapeutic compounds for the treatment of bacterial diseases than available at present, recovery will continue to depend largely upon immunological processes aided in some diseases by biological therapy (vaccines, serums, blood transfusion, etc.). The question naturally arises whether or not it is possible for us to aid Nature in her immunological processes by the administration of drugs? In other words, may drugs to be classed in the domain of chemotherapy increase antibody production or aid and facilitate phagocytosis in bacterial diseases?

We hear and read a good deal about arsphenamin and its congeners increasing antibody production or aiding immunological processes in syphilis

and trypanosomiasis, but the evidence presented so far is not very convincing, as I shall discuss with more detail in Chapter XII. In bacterial diseases, however, acquired immunity is developed to a greater degree and plays a far more important part in recovery than in syphilis and anything that may be safely done to hasten or increase these beneficial changes is to be welcomed.

In the first place, the intravenous administration of mercurochrome, other heavy metals and some of the dyes, quinin compounds, etc., commonly employed at present in bacterial chemotherapy, may increase the leukocytes of the blood and especially the polymorphonuclear neutrophils which we regard as playing a very important part in natural and acquired resistance and immunity. The doses required, however, for this result are usually the maximum amounts by intravenous injection. Unquestionably it is reasonable to expect that these leukocytes will prove of aid in overcoming the infection and the clinical reactions following the intravenous injection of mercurochrome and other heavy metals, bears such a close resemblance to the so-called non-specific protein reactions produced by the intravenous injection of peptone, vaccines, etc., that one cannot escape the suspicion that a goodly part of the curative results may be due to the same mechanism as called into play by the administration of these protein agents.

But I have had so far no clear or conclusive evidence of the increased production of such humoral antibodies as the antitoxins, agglutinins, precipitins, opsonins and bacteriolysins during the course of experimental or natural bacterial infections, to be ascribed to the influence of such drugs as optochin, gentian-violet, acriflavin and mercurochrome. It may be that such compounds actually stimulate the production of antibodies, since the production of leukocytosis indicates that the bone marrow and the antibody-producing tissues in general may be stimulated, but it is difficult or impossible with present test tube methods to elicit and present the evidence. It is true that the administration of these compounds to normal animals may increase temporarily their resistance to bacterial infection in a manner analogous to the temporary resistance of mice and rats, treated with some of the dyes, to inoculation with pathogenic trypanosomes, but the resistance is of such short duration that one cannot be sure that the results are not due rather to a retention of some of the compounds in the blood and tissues than to an increase of immunological resistance.

However, we do have some evidence to indicate that optochin, at least, and possibly also gentian-violet and mercurochrome may aid phagocytosis *in vivo* by lowering the resistance of the organisms. This is especially true in the treatment of local infections by topical application, but in this connection one must remember the possibility of paralyzing the leucocytes and retarding phagocytosis by the use of too strong solutions.

It may be, therefore, that some of our chemotherapeutic compounds may actually aid in immunological resistance and recovery from experimental and natural bacterial diseases of human beings and the lower animals, not so much by the actual stimulation of production of humoral antibodies, as by lowering the resistance of bacteria to phagocytosis, by the production of leukocytosis, a febrile reaction and other changes now so well known clinically as the "non-specific protein reaction."

Combination Chemotherapy and Biologic Therapy of Bacterial Diseases. This raises the question of the practical value of combining chemotherapy with such biologic therapy as the administration of immune serums, vaccines, non-specific protein agents and blood transfusion, in the treatment of bacterial diseases. All of my clinical experience indicates that best results are

to be obtained by the judicious use of both kinds of therapy in the treatment of bacterial diseases and especially the acute infections. Chemoserotherapy, or the combination of chemotherapy with serum therapy, has been before the profession for several years and is deserving of the closest study and attention.

After all, we are more interested in the recovery of our patient than in figuring out in exact terms to what recovery may be ascribed and I rarely depend upon chemotherapy alone in the treatment of the acute bacterial diseases, but always include serum therapy, blood transfusion or vaccine therapy when indicated, as will be discussed and presented in Chapter VIII, devoted to the practical chemotherapy of bacterial diseases. In other words the chemotherapy of bacterial diseases has not progressed by any means to the stage where we can afford to neglect surgery, biological therapy or any other helpful therapeutic means for winning the battle with infection. For example, I rarely neglect to use antistreptococcus serum in the treatment of acute streptococcus infections with septicemia along with gentian-violet or mercurochrome. I am likewise very partial to transfusions of blood and especially in the treatment of long continued and exhaustive infections associated with anemia. But I shall reserve for Chapter VIII a fuller discussion of this important subject, wishing here to merely direct attention to the important subject of judiciously combining chemotherapy with biologic therapy in the treatment of the bacterial infections. Even the administration of vaccines and non-specific agents may be of aid because of their administration may produce mild focal reactions about the diseased parts characterized by hyperemia and serous exudation which may facilitate the penetration of a chemotherapeutic compound in the blood and prove generally useful when due care is exercised in dosage to avoid excessive hyperemia and exudation. I also surmise that judicious tuberculin administration to produce *mild* focal reactions of this kind may ultimately prove a useful adjuvant to the chemotherapy of tuberculosis, since the hyperemia and exudation may encourage the much to be desired penetration of tubercles by tuberculocidal chemical agents brought to the infected tissues by the blood.

As I shall point out in Chapter VIII, the combination of antipneumococcus serum with optochin has yielded better results in the treatment of experimental pneumococcus infections of mice than either optochin or serum alone and I have observed similar results with antistreptococcus serum and gentian-violet and the serum and mercurochrome, in the treatment of experimental streptococcus infections of the lower animals. The same has been observed in the treatment of anthrax and other bacterial infections, so that the combination of immune serum therapy and chemotherapy is recognized as distinctly useful in the treatment of a number of acute bacterial diseases.

Possibilities of Chemotherapy in the Bacterial Diseases.—Finally I may conclude this chapter by a brief reference to the possibilities for developing a specific chemotherapy for the bacterial diseases. As will be pointed out in the succeeding chapters a great deal of useful work has been done with the dyes, heavy metals, quinin and a host of other substances and the results have not been entirely fruitless or lacking in encouragement. I by no means share the skepticism so frequently expressed in regards to the future of the chemotherapy of bacterial diseases if money and interested workers are available for the tremendous expense and labor required for advancing our knowledge. It is true that more, much more, advance has been made in the chemotherapy of protozoal and metazoal diseases and that the problems of bacterial diseases are apparently more difficult, but when one considers

the advances made during the past five years it is neither rash nor unwise to expect greater discoveries in the future as the fruit of hard, conscientious and unremitting, but systematized toil coupled with the ever alluring chance of making a "lucky strike." A larger appreciation of the possibilities of chemotherapy in the bacterial diseases should lead to a greater expenditure of brains and money as being warranted by the importance of the problems and the prospects of valuable results; as so well stated by the late Morgenroth:[4]

"What yesterday seemed absurd, tomorrow will seem banal. Today it is no longer a question for debate whether or not there can be a prophylactic and curative chemotherapeutic antisepsis, but merely a question of when, where and how. The future of chemotherapeutic antisepsis will probably resemble the present situation in respect to local and general anesthesia, for the future surgeon will inquire in each case whether the antisepsis should be local or be general through the circulation, which antiseptic is to be selected, what concentration and quantity, etc., just as he now does with his anesthetics."

CHAPTER IV

METHODS FOR CHEMOTHERAPEUTIC INVESTIGATION IN BACTERIAL AND MYCOTIC DISEASES

The principles and technic of methods employed in chemotherapeutic investigations in bacterial diseases are subjects of considerable importance and deserving of closer attention and analysis than they have generally received. It is the general impression, for example, that bacteriostatic and bactericidal tests *in vitro* with new compounds are of little or no real value in relation to the actual treatment of disease; this, however, is far from being true although not infrequently new compounds, rushed into clinical use on the basis of tests *in vitro*, have yielded disappointments largely because the methods employed were woefully lacking in proper appreciation of essential principles in technic.

Much time and useless duplication of effort would be saved by the adoption of standard methods enabling different workers to better compare results, but at the present time almost every investigator in this field has employed a method or methods varying to a greater or lesser degree from the methods of others; this, however, is not nearly as important as the wider recognition of the essential principles involved as well as of the advantages, disadvantages and limitations of various methods. The very nature of chemotherapeutic research demands that there shall be available a variety of methods, but it is imperative that the purposes and principles of the methods are properly understood and appreciated in order to avoid the regrettable error of drawing unwarrantable conclusions and too hasty acceptance or condemnation of new compounds.

Classification of Experimental Methods in Bacterial Chemotherapy.—In the first place, it may prove helpful to classify the different tests and methods that may be employed in chemotherapeutic research in bacterial diseases.

Naturally the earliest and best known of these are various *in vitro* methods for determining the effects of a chemical agent upon bacteria under artificial conditions and two principal kinds are employed, namely, (*a*) *antiseptic or bacteriostatic methods* for determining the smallest amount of agent capable of restraining the growth of organisms over a given period of time and (*b*) *bactericidal methods* for determining the smallest amount of agent capable of killing organisms in a given period of time. Each has a useful place in chemotherapeutic research as will be shortly discussed, although the bactericidal tests are the more important and have a closer relation to the chemotherapy of bacterial diseases when arranged and conducted with a definite purpose in mind. For example, if a compound is being developed primarily for the local disinfection of wounds, tests of this kind should be conducted with a menstrum rich in the proteins and salts of the blood and muscles; if it is designed primarily for the treatment of infections of the urinary system, tests conducted with sterile urine are useful and if for systemic infections, the tests should be conducted with serum or, better still, with whole blood, etc. Bacteriostatic tests must be conducted with a suitable culture medium, since it is necessary that the organism shall survive and multiply unless restrained by the chemical agent under study, but the medium may also contain blood, serum, ascites fluid, muscle extract, etc.

In vivo methods are designed for testing out the effects of a compound in living animals infected with a particular organism. As a general rule, they are only conducted after the toxicity or organotropism of the compound has been determined and preferably for the same species of animal. Tests of this kind may be divided into two main varieties, namely, (*a*) *protective tests*, in which the drug is administered shortly before, with or shortly after inoculation and (*b*) *curative tests*, in which the infection is given a good start with the production of bacteremia and lesions of the fixed tissues before the drug is administered. Needless to state, the protective kind of test is usually more favorable to the compound than the curative test because the number of organisms requiring destruction is smaller and time is not permitted for the production of modifying pathological changes in the tissues.

Protective and curative tests may be conducted with either generalized (systemic) or localized infections. The former have been generally employed, but the latter, like pleuritis, arthritis, meningitis, dermatitis, etc., are sometimes especially useful although it may be difficult or impossible to produce experimentally a strictly localized infection of the serous cavities like those of joints, pleurae, pericardium or subarachanoid space.

Another type of *in vivo* test consists of administering the compound and testing the blood at intervals for increased bactericidal effects by removing small amounts under sterile conditions, seeding with a test organism and plating the mixtures after suitable intervals. This might be designated as a *combined in vivo and in vitro method*, and serves a useful function in chemotherapeutic research. The reverse of this method is also sometimes useful, consisting of adding the organism to the disinfectant agent *in vitro* and after a suitable interval injecting a portion of the mixture into a susceptible animal for determining the degree of bactericidal activity. This is likewise a *combined in vitro and in vivo method* which has been found useful in studies upon the chemotherapy of pneumococcus, streptococcus and other bacterial infections, as well as in chemotherapeutic investigations with pathogenic trypanosomes and spirochaetes.

All of these tests are governed by certain fundamental principles and possess certain advantages as well as disadvantages in relation to the subject of chemotherapeutic research and before the methods are described it may

be well to briefly summarize these subjects in order that their value and limitations shall be defined at the outset.

Value of Bacteriostatic and Bactericidal Tests in Vitro in Relation to Chemotherapy.—In the rational development of the chemotherapy of bacterial infections it is desirable, if possible, to commence experimental work with a substance or substances possessing some definite destructive effect on the microparasite under study. This parasitotropic effect may be apparent only in test-tube experiments; in such event, an effort is made to lower the toxicity or organotropic effect of the substance, with, or even without, an increase of its parasitotropic power, in order that it may be administered in such quantity as will exert in the living animal an inhibitory or killing action on the microparasite under study without injury to the host.

In chemotherapeutic studies on bacterial infections, experiments *in vitro* may be said to have a positive value in preliminary orientation in the development of leads and the study of new compounds as they are produced. Experimental data at hand tend to show that substances possessing a high bactericidal activity *in vitro*, and particularly in a menstrum of fresh sterile serum, are likely to exert an inhibitory effect *in vivo*. For example, Morgenroth's drug, optochin (ethylhydrocuprein), and its hydrochlorid exert a very high bactericidal action on the pneumococcus *in vitro* and are likewise effective to some extent *in vivo;* other cinchona derivatives, including certain salts of quinin, possessing more or less bactericidal value *in vitro* are likewise effective to a certain degree *in vivo*.

Unfortunately, however, numerous substances possessing a high degree of bactericidal activity *in vitro* and even in a menstrum of serum or blood, may fail to influence an infection *in vivo*. Indeed, since the time of the earliest discoveries in bacteriology and of bactericides, substances highly bactericidal in the test tube have been known to fail to exert any appreciable influence *in vivo* when given in safe doses. This lack of effect may be due to the high organotropic or toxic effect of the substance on the body cells in general or on a particular group of cells of vital centers, precluding the use of a bactericidal quantity; to insolubility and difficulty of administration; to rapid union with the proteins of the body and the formation of inert compounds; to rapid elimination; to failure to reach the microorganism in a lesion, and to still other causes. Of the possibilities the first mentioned is of primary importance; but the method and manner of attack of the bactericidal drugs on the protoplasm of cells, aside from coagulation, is almost unknown. Nevertheless, it is possible by systematic modification of the molecule through addition, removal, or substitution of certain atom groups, to produce in some instances a sufficient lowering of toxicity to give an available therapeutic agent. The demonstration of this fact constitutes the great triumph of Ehrlich and opens a fascinating field of research to chemist and biologist.

It is highly probable that experimental studies tending to increase the monotropism of a drug *in vitro* and particularly in a menstruum of serum will prove of value in chemotherapeutic work. On the other hand, a substance failing to exert parasitotropic action either *in vitro* or *in vivo* may still prove of value as a basis of composition, and offer a valuable lead in chemotherapeutic research. Likewise, it is possible that a chemical may be more efficacious *in vivo* than *in vitro* by reason of the formation of new and more active compounds *in vivo;* or by exciting the body cells to produce antibodies for the parasitic antigen or chemically facilitating such production as by the stimulation of phagocytosis or some other effect upon immunological processes.

It is highly probable, therefore, that experiments *in vitro* have a definite value in chemotherapeutic research as methods of preliminary orientation

and in the development of monotropic chemicals. This value is greater when the identical microparasite causing the definite infection under study is employed in the tests. In the absence of a pure culture of the particular microparasite against which a destroyer is sought, or in the presence of insuperable technical difficulties, other and more easily cultivated organisms closely or remotely related, or even of a different biologic order, may be employed.

Principles and Special Requisites of Bacteriostatic and Bactericidal Tests in Relation to Chemotherapy.—It is well known that many factors influence the results of bactericidal tests, and many investigators, notably Rideal and Walker,[1] and Anderson and McClintic[2] have sought to establish standard methods for the bacteriologic standardization of disinfectants. Consideration of the physical and chemical laws underlying the action of chemicals on bacteria *in vitro* are to be found in their papers, and in that of Phelps,[3] Chick[4] and others, the work of Miss Chick being especially valuable for showing that in all essential particulars the act of disinfection may be regarded as obeying the laws governing a simple chemical reaction, in which the disinfectant represents one reagent and the bacteria the other.

For chemotherapeutic studies two main kinds of *in vitro* tests may be employed: (1) a simple technic observing the first principles governing these reactions, particularly a uniform temperature, and employing an easily cultivated microorganism, as *B. typhosus* or *Staphylococcus aureus;* or (2) a technic aiming at conditions more closely approximating those operative in the living animal.

As a result of a large amount of work with various methods, one fact stands out clear, and that is the necessity of adopting a uniform technic. The most marked variations in bactericidal power appear as the test methods employed are varied. For this reason Cohen, Heist and I[5] have studied various methods quite extensively and those herein described are partly based upon the results of our work with the pneumococcus.

With certain microörganisms, as *B. typhosus* and staphylococci, either the Hygienic Laboratory or the Rideal-Walker method may be employed to determine the bactericidal action of new compounds developed in the course of chemotherapeutic studies. But these methods are not adapted for work with microörganisms less hardy and requiring special culture media, as the pneumococcus, gonococcus, and streptococcus. Furthermore, it has appeared to me that for the special purposes of chemotherapeutic study an acceptable method should approach as nearly as possible the conditions presented in the living animal, particularly with reference to temperature.

Here may be summarized what may be considered the essentials of an acceptable *in vitro bactericidal test* for the special purpose of chemotherapeutic studies in bacterial infections:

1. The test should be conducted at a temperature of 37°C. instead of 20°C. in order to approach more nearly conditions in the living animal. The influence of temperature on the chemical reaction between bacterium and bactericide has been uniformly emphasized and constitutes a very important factor. The velocity of disinfection is known to increase with rise in temperature in a manner similar to that of an ordinary chemical reaction.

2. The solution of chemical should contain some organic matter, as the protein of broth, sterile inactivated serum, or ascites fluid. Wide variations in bactericidal power are noted according to whether the menstruum is serum, pus, or salt solution, as will be shortly discussed.

When large numbers of new compounds are to be tested at frequent intervals, and particularly in an effort to build up a monobacteriotropic chemical, the simpler technic fulfilling at least the fundamental laws of chemical reaction and utilizing sterile water or salt solution as the menstruum, may be employed; but when an effort is being made to obtain from *in vitro* tests data of greater value in relation to the probable effect of a given parasitotrope *in vivo*, serum or blood are to be preferred.

3. In the chemotherapeutic study of a definite infection the causative microorganism should be employed whenever possible.

It would also appear advisable to employ a freshly isolated culture from human or experimental lesions in the conduct of certain tests which aim to be conclusive. This has been found especially true of the pneumococcus. The presence or absence of capsules and the degree of virulence of the strain for white mice and rabbits appear to influence markedly the results of tests *in vitro*. For routine tests, however, it is better to employ a uniform and known culture or cultures well adapted for growth under artificial conditions, but preferably retaining some degree of virulence.

4. It is necessary to employ in the tests a sufficient number of microörganisms to yield well-defined results. In work with the pneumococcus and similarly less hardy bacteria, appropriate culture media must be employed and frequent counts made by the plating of twenty-four hour cultures to determine the approximate numbers of living microorganisms present.

Tests may be conducted after ordinary methods with low concentrations of the chemical over long periods of time, with apparent inhibition of the microorganism which may amount to true killing (the "bacteriostatic" test); or with higher concentrations but shorter periods of exposure, and a definite attempt to determine whether or not killing has resulted (the "bactericidal" test). Plating methods attempt to measure the degree of bactericidal activity after a definite exposure to varying concentrations of the chemical, according to the number of bacteria killed.

As pointed out by Phelps and amply confirmed by Cohen, Heist and myself, bacteriostatic power, or true disinfection at low concentrations for long periods, may show a relation between two chemicals quite different from that shown at higher concentrations and shorter periods of exposure. One compound may be a superior bactericide in high concentration and lose rapidly in efficacy with dilution and hence prove to be a poor antiseptic; while the other, though of lesser value in high concentration, retains its power better with dilution.

Various Menstrums for Bacteriostatic and Bactericidal Tests in Vitro in Relation to Chemotherapy.—The selection of the menstrum or medium with which the disinfectant and organism are brought together is a matter of considerable importance. Almost without exception a medium of serum, blood, muscle extract, etc., greatly reduces germicidal activity in both short and prolonged exposures. As stated by Dakin and Dunham[6] the capacity of a disinfectant to kill organisms is dependent to an extraordinary degree upon the conditions under which it acts. Almost invariably the greatest antibacterial activity is shown when the substance acts upon bacteria freed from culture media and suspended in distilled water or salt solution. They have found the activity of mercuric chlorid against staphylococci in a hard tap water to be only one-fifth of that shown when distilled water was employed, while with silver salts the results were even more liable to variation.

The presence of 50-per cent. serum reduces bactericidal activity approximately 5 to 200 times depending upon the compound. In the presence of pus, in which many bacteria are partly infested in the bodies of the dead leukocytes and hence difficult to attack, the results are still less favorable as shown by Morgan[7] and others.

It is stated that some derivatives of hexamethylenetetramin are less affected by serum and according to Browning[8] one compound known as trypaflavin or acriflavin is about ten times more bactericidal in serum than in peptone solution. I have observed that 5 c.c. of a final dilution of 1 : 800 of acriflavin in 50 per cent. horse serum killed staphylococci (1 c.c. of 18 hours broth culture) in fifteen minutes at room temperature while 1 : 500 in sterile peptone water gave the same result. After an exposure of one hour, however, the results were almost identical, being about 1:800 in both menstrums.

The selection of the menstrum or medium for tests of these kinds is largely controlled by circumstances and according to the kind of information desired. For routine purposes and to determine bacteriostatic and bactericidal activities under the most favorable conditions, either plain nutrient broth, saline or Locke's solutions may be employed; if however, the disinfectant is designed for use in the treatment of infected wounds or serous cavities it is advisable to employ menstrums of muscle extract, serum or pus; if designed for administration by intravenous injection, menstrums of blood or serum are advisable; if designed for use in the genito-urinary tract by local application, a menstrum of sterile urine, etc., may be employed. In other words the choice of medium should be influenced by our therapeutic designs for the agent under study and one should carefully avoid basing conclusions on the results of tests employing saline solution or water, as bearing upon the disinfection of an infected wound, an infected serous membrane, the blood, etc.

Due care must be also exercised in guarding against the selection of a menstrum in itself bactericidal. Thus some organisms may perish in plain distilled water and especially if the exposure is prolonged; some organisms like the meningococcus may even perish in saline solution. Fresh defibrinated blood and fresh serum may prove in themselves slightly bactericidal and especially for organisms of the colon-typhoid group. It may be necessary, therefore, to keep these factors in mind when working with certain organisms.

Phenol and Mercuric Chlorid Coefficients.—So many factors may appreciably influence bacteriostatic and bactericidal tests *in vitro* that it is almost hopeless to expect different workers to obtain identical results. The slightest change in the reaction of the culture medium and indefinable changes in the test organism are the chief sources of variation. Only in the simplest methods and by strict attention to every detail including the use of the same culture, may different workers obtain approximately the same results as with the Rideal-Walker or Hygienic Laboratory phenol coefficient methods.

For these reasons I believe that a control and standardized disinfectant like phenol or mercuric chlorid should be used in every bacteriostatic or bactericidal test and the results observed with a new compound expressed in terms of comparison with the standards. For this purpose, a titrated and standardized 5-per cent. solution of pure phenol may be employed for preparing dilutions; I believe this standard is well adapted for tests with chemical compounds of relatively low bactericidal activity. For testing new compounds of mercury, copper, silver, etc., possessing a higher bactericidal activity *in vitro*, a chemically pure mercuric chlorid is advisable. This substance apparently does not change if properly sealed and furnishes a fixed standard for comparative purposes.

For example, the highest bacteriostatic dilution of a new mercurial compound may be 1:800,000 and bichlorid 1:480,000; the *bichlorid index* or *coefficient* would be expressed as plus 1.66. When these substances are tested again at a later time in apparently the same manner and using the same organism, the bacteriostatic dilutions may be different like 1:1,000,000 and 1:650,000 respectively; however the bichlorid index is plus 1.5 which is about as near as one may expect in work of this kind. A new compound may be bacteriostatic in 1:80,000 and bichlorid in 1:400,000; the index in this case is expressed as minus 5.0, the plus sign indicating that the new compound is more and the minus sign that it is less, in bacteriostatic or bactericidal activity than mercuric chlorid. Phenol may be used in the same manner. I have used this method for over ten years in bacteriostatic

and bactericidal tests and for expressing results and can highly recommend it, because the factors tending to raise or lower the titers of a new compound like variations in the culture medium or organism, exert the same influence upon the control bichlorid or phenol and thereby yield approximately the same coefficients or indices.

Technic of in Vitro Bacteriostatic Methods.—The purpose of bacteriostatic tests is to determine the highest dilution of a chemical agent capable of restraining the growth of the test organisms for a stated period of time; this may finally amount to a complete destruction of all of the organisms and especially in the lower dilutions while in the higher dilutions only proliferative activities or genesistasis is inhibited, the organisms being found alive when removed by subculture. Tests of this kind are much simpler than bactericidal tests and the results are usually very sharp and definite; I can highly recommend them for routine work and especially when it is desired to ascertain if a new compound displays any specific parasitropism for a particular kind of organism and how it compares with either phenol or mercuric chlorid in any stated medium or several mediums. The technic is so simple that tests may be conducted simultaneously with several organisms or several mediums for routine studies.

Author's Method Employing Nutrient Bouillon.—For tests with staphylococci, *B. anthracis*, *B. typhosus*, *B. coli* and such hardy organisms, plain beef extract broth with a pH of 7.1 may be employed; Kligler has used a medium prepared of 1-per cent. Fairchield's peptone, 0.5-per cent. dibasic potassium phosphate, 0.5-per cent. sodium chlorid and 0.1-per cent. glucose with a constant pH of 7.1. The reaction of any medium employed is particularly important as the results may be greatly modified by this factor. For streptococci and pneumococci harmone broth (Huntoon) with 0.1-per cent. dextrose and a pH of 7.7 is to be preferred and for tubercle bacilli, the ordinary 5-per cent. glycerin harmone broth employed in the manufacture of Koch's tuberculin should be used. *It is always advisable to determine beforehand that the organism will grow well in the medium employed before the tests are conducted.*

(1) As a general rule, 10 dilutions are advisable and for this purpose 10 sterile test tubes are arranged for each compound including a set for the bichlorid of mercury or phenol controls.

(2) In all tubes except No. 1 of each series, place 1 c.c. of sterile distilled water.

(3) In tubes 1 and 2 place 1 c.c. of the stock solution of disinfectant which is 10 times higher than the final dilutions desired. Mix No. 2 and transfer 1 c.c. to No. 3 and so on to No. 10 from which discard 1 c.c.

(4) In a flask of 99 c.c. of the culture medium place 1 c.c. of a twenty-four to forty-eight hour broth culture of the test organism; with such organisms as streptococci and pneumococci it is well, however, to seed by mixing 5 c.c. of a broth culture with 95 c.c. of the culture medium. Mix well and add 9 c.c. to each tube of the set; the remaining 10 c.c. is placed in a sterile tube as a control on the culture.

(5) In tests employing tubercle bacilli, it is better to add 9 c.c. of sterile medium to each tube and then to seed by floating a loopful of bacilli on the surface of each.

(6) The final dilutions are now 10 times higher in each tube; for example, 1 c.c. of 1:1000 stock solution in No. 1 becomes 1:10,000 and the final dilution in No. 10 is 1:5,120,000.

(7) The tubes are incubated and the results recorded daily for five days. When the medium remains clear the result is recorded as *minus;* when a visible growth appears the result is recorded as *plus*. At the end of this period the tubes may be cultured by transferring several loopsful to slants of a solid medium to determine whether the organisms have been killed or merely restrained. In this manner a bactericidal test is conducted at the same time in which a few organisms have been exposed to the disinfectant for five days. The control should be subcultured at the same time to make sure that the organisms are viable.

(8) The results are expressed according to the highest bacteriostatic and bactericidal dilutions and also according to the bichlorid or phenol coefficients previously described.

(9) After obtaining in this manner an approximate idea of the activity of the compound under study, a second series of dilutions are prepared in which the variations from tube to tube are less marked.

Author's Method Employing Serum, Blood, Ascites Fluid or Muscle Extract.—These tests are conducted in exactly the same manner as described above except that to 89 c.c. of a suitable broth medium are added 10 c.c. of sterile serum, blood or ascites fluid; the mixture is

then seeded with 1 c.c. of a broth culture of the test organism; with such organisms as the pneumococcus and streptococcus however, it is generally advisable to use 8.5 c.c. of both, 10 c.c. of serum, blood or ascites fluid with 5 c.c. of broth culture of the test organism. This gives a 10-per cent. solution of serum, blood or ascites fluid and while more or less may be employed as desired, yet experience has indicated that the above is satisfactory for eliciting the influence of these substances upon the degree of antibacterial activity of disinfectants.

Numerous experiments have shown that while the bacteriostatic and bactericidal activity of various disinfectants is reduced to a greater extent on a 50 per cent. than a 5-per cent. dilution of serum, defibrinated blood, or ascites fluid, yet for all practical purposes a 10-per cent. solution is satisfactory for this purpose and in view of the large amounts required is to be preferred from the standpoint of economy. With muscle extracts, however, it may be advisable to use equal parts with broth (50-per cent.), but muscle extract may be prepared so cheaply and quickly as required that the questions of economy and supply are not involved. These preparations are likewise slightly cloudy but not usually to a degree sufficient for interfering with the ease and accuracy of readings. I may add in this connection however, that a menstrum containing 10-per cent. of a muscle extract prepared of ordinary beef or veal requires a far higher concentration of disinfectants than a menstrum of 10-per cent. blood or serum; this is doubtless due to the presence of large numbers of various bacteria in addition to the test organism.

Other special mediums like harmone dextrose broth with brain tissue, ascites broth with sterile kidney, etc., may be employed in tests of this kind and while the results vary according to the constitution of the medium, yet if mercuric chlorid or phenol are included in each and every test, the results may be expressed in terms of the coefficients or indices. The coefficients, however, will vary according to the chemical nature of the compound as this is influenced by the constitution of the medium; for example, some compounds of mercury like mercurophen and metaphen, maintain a higher degree of bacteriostatic activity in a serum, blood or brain medium than mercuric chlorid and thereby yield higher coefficients. In other words while the bactericidal activity of almost all disinfectants is reduced in the presence of serum, blood, muscle extract, etc., the degree of reduction varies considerably among different compounds.

Author's Method Employing Solid Mediums; Mycostatic Test.—It is very easy to employ solid culture mediums in this technic and for such organisms as grow better on solid than fluid medium, as the various yeasts and molds, the former are to be preferred.

In conducting this test, a series of dilutions of the disinfectant in amounts of 1 c.c. in sterile distilled water are prepared in sterile test tubes as previously described. To each tube and a control are now added 9 c.c. of an appropriate agar medium cooled to 42°–45°C.; the contents are well mixed and allowed to harden in slants. The dilution in each tube is now ten times higher; or 4 c.c. of medium may be added to each tube which renders the final dilution in each tube 5 times higher.

For such organisms as staphylococci, *B. typhosus*, *B. coli*, etc., plain 2-per cent. agar (pH 7.1) may be employed; for streptococci and pneumococci a harmone dextrose (0.1-per cent.) agar with a pH of 7.7 is to be preferred. For tubercle bacilli a glycerine agar may be employed since an egg medium may be unsatisfactory because heating for inspissation and sterilization may break up some disinfectants. For parasitic molds like *Trichophyton rosaceum*, *Microsporon audouini* and *Achorion schoenleinii*, Sabouraud's maltose medium titrated to 1-per cent. acid to phenolphthalein, may be employed. Whatever medium is chosen, it must be adapted for cultivating the test organism, should be sterile, liquified by heating and added to the tubes containing varying dilutions of the disinfectant while still fluid after being cooled to 40°–45°C. After hardening has occurred, each tube is inoculated in as uniform manner as possible and the tubes incubated for a period of 5 to 10 days (mycostatic tests for 2 weeks or longer at room temperature) as decided upon. The results are expressed according to the highest dilution of disinfectant capable of preventing the growth of the test organism. Mercuric chlorid or phenol controls may be included and the results expressed in terms of coefficients.

Technic of in Vitro Bactericidal Methods.—From the standpoint of chemotherapy the results of bactericidal tests probably possess a more direct value and application than bacteriostatic tests because the duration of disinfection of the living tissues is almost always a process of short duration. A very large number of different methods have been proposed from time to time but the older "thread" method of Koch and the "garnet" method of Kronig and Paul are not now generally used. No single method can serve as a means of comparing the value in practice of disinfectants of greatly diverse composition and destined for a variety of applications, but as

a general rule a satisfactory method may be easily devised to meet special conditions if the primary and fundamental principles are kept in mind.

For disinfectants chemically related to phenol, which are to be used against organisms reacting similarly to the manner in which the typhoid bacillus reacts and which are destructive within fifteen minutes at 20°C., the Rideal-Walker or Hygienic Laboratory methods may be employed. The results may be useful in the selection of a potent product, in making comparisons of cost in terms of service rendered, and in checking successive batches of the same product. I shall omit here the technic of the well known Hygienic Laboratory method as recently described[9] and proceed with the description of methods which I have found of more value in relation to chemotherapeutic investigation in bacterial diseases.

Author's Bactericidal Tube Method.—The principle of this method is to determine approximately the highest dilution of disinfectant proving completely bactericidal for large numbers of organisms in exposures of 5, 30 and 60 minutes at 38°C. The method is adapted for conducting tests in any menstrum as water, broth, serum, blood, ascites fluid, muscle extract, urine, etc., and the intervals of exposure may be modified at will.

1. For each disinfectant arrange 10 sterile test-tubes, the first 9 carrying 1 c.c. of varying dilutions in sterile distilled water 5 times stronger than the desired final concentrations; the tenth tube carries 1 c.c. of sterile water for a control.

2. In a small sterile flask or glass stoppered cylinder place 10 c.c. of the chosen menstrum as sterile distilled water, saline, broth, serum, ascites fluid, defibrinated blood, urine, muscle extract, etc. Add 20 c.c. of sterile distilled water and mix.

3. Add 10 c.c. of a twenty-four hour plain meat extract or harmone broth culture of the chosen organism filtered through sterile paper (as *B. typhosus*, *B. para-typhosus*, *B. coli*, *B. pyocyaneus*, *B. prodigiosus* or *Staphylococcus aureus*). Streptococci and pneumococci may be cultivated in 0.1 per cent. dextrose harmone broth but the addition of serum or a tissue (brain) should be avoided if the tests are to be conducted in a plain menstrum. Otherwise these organisms and *B. tuberculosis* may be cultivated on a solid medium or centrifuged out of a fluid medium and a homogenous suspension in plain broth or saline solution prepared containing at least one hundred million organisms to the cubic centimeter. As a general rule a suspension of *B. anthracis* of this kind is better than a broth culture. The suspension should be shaken with sterile beads for at least one-half hour to break up clumps (tubercle bacilli should be first triturated in a sterile mortar) and finally filtered through a rather coarse fat free sterile paper.

4. Mix well and add 4 c.c. to each of the 9 tubes carrying varying dilutions of disinfectant and the balance to tube No. 10 which is the culture control.

The final dilutions of disinfectant in each tube are now five times higher; for example, 1 c.c. of a 1:100 solution in tube No. 1 now has a final dilution of 1:500 acting on the organisms in a 20-per cent. solution of the chosen menstrum (water, saline, broth, serum, blood, muscle extract, etc.). The tubes should be plugged in the usual manner to prevent air contamination.

5. Note the exact time when the mixtures are made; keep the tubes in a water-bath at 38°C. and at intervals of 5, 15 and 60 minutes subculture two loopfuls to either slants of appropriate solid medium or to tubes of a suitable fluid medium (10 c.c. in each), the choice of medium depending upon the organism being employed (as plain extract broth or agar for staphylococci, typhoid, colon, and anthrax bacilli; egg medium for tubercle bacilli; blood agar or serum dextrose broth for streptococci, pneumococci, etc.). Instead of seeding with a platinum loop it is permissible to use a capillary pipet for transferring 1 or 2 drops, the pipet being sterilized between transfers by several washings with boiling water.

6. Include a series of tubes carrying dilutions of phenol or mercuric chlorid as controls for expressing the results in comparison with these disinfectants.

7. The test may be shortened by subculturing at any one interval that may be chosen as at the end of 2, 5, 10, 15, 20, 30 minutes or longer periods; for exposures of two hours or more the incubator may be employed instead of a water bath.

8. Incubate the subculture seed tubes for 24 to 72 hours (10 days or longer for tubercle bacilli) and record the results if the culture control has shown a satisfactory growth.

9. The results are expressed according to the highest *final* dilution of disinfectant proving completely bactericidal at any one, all three or more of the time intervals chosen; for any one or all of these intervals the results may be also expressed according to phenol or mercuric chlorid coefficients.

Author's Bactericidal Plating Method.—The primary purpose of this method is to determine the rate of bactericidal activity over any period of time in any chosen menstrum and preferably at 38°C. It is advisable to know beforehand the approximate activity of the

compound under study which may be determined by the tube method described above. The test is only applicable for such organisms as may be readily plated out in plain or serum agar.

1. For tests employing *Staphylococcus aureus, B. typhosus, B. coli, B. anthracis* and such organisms as grow readily in plain agar, five tubes containing 10 c.c. each of plain or harmone agar should be boiled and kept in a water bath at 45°C. For streptococci and pneumococci a serum harmone agar may be prepared by adding 1 c.c. of sterile serum to tubes of harmone agar after they have been boiled and cooled to 45°C.

2. Arrange five sterile petri dishes.

3. In a sterile test tube place 2.5 c.c. of sterile distilled water, 1 c.c. of the chosen menstrum (sterile water, broth, serum, defibrinated blood, urine, muscle extract, etc.) and 0.5 c.c. of broth culture or suspension of the chosen test organism prepared as described above for the tube method.

4. Place the mixture in a water-bath at 38°C. for several minutes and then add 1 c.c. of a solution of the disinfectant in sterile water 5 times higher than the chosen final solution. For example, 1 c.c. of a 1:200 solution would give a final dilution of 1:1000. Use a sterile 1 c.c. pipet and wash by drawing in and expelling the mixture several times, noting the time when the organisms are added. It is always imperative to add the disinfectant last and especially when labile substances like chlorin antiseptics are being tested for otherwise the rate of chemical reaction taking place between the unstable antiseptic and organic menstrum may be a more important factor than the rate of bactericidal activity of the substance under study. Mix the contents and plug the tube in the usual manner to prevent contamination.

5. In a second tube place 1 c.c. of the culture, 1 c.c. of the menstrum and 3 c.c. of sterile distilled water; mix, plug and place in the water bath. This is the culture control.

6. At chosen intervals like 5, 15, 30 and 60 minutes place 0.05 c.c. of the mixture carrying disinfectant in a sterile petri dish. For this purpose a sterile 1 c.c. pipet may be used, being washed out between transfers with boiling water. Instead of these intervals one may chose 1, 15, 30 and 60 minutes or 5, 30, 60 minutes and 2 hours, etc.

7. Add a tube of the agar medium and mix thoroughly. After hardening the plates are incubated upside down for forty-eight hours and the colonies counted in the usual manner.

8. The control is cultured in the same manner at the end of 60 minutes. However, plates may be prepared at the same intervals as the disinfectant mixture; this would require the preliminary preparation of three more petri dishes and three more tubes of culture medium.

9. One drawback to all plating methods is the possibility of carrying over to the plates a sufficient amount of the disinfectant to produce bacteriostasis. For example, if a final dilution of mercuric chlorid 1:1000 or some equally potent bactericide were being tested in a plain menstrum, plating 0.05 c.c. with 10 c.c. of agar would give a final dilution of approximately 1:200,000 which may prove sufficiently bacteriostatic for yielding very erroneous results. This error may be avoided by using the highest final dilution of disinfectant likely to be completely bactericidal in one hour as determined in a preliminary tube test in order to carry over the minimum amount of disinfectant. Otherwise, an antidote may be added to each petri dish at the time of plating to neutralize the disinfectant, as 1 c.c. of a sterile 1-per cent. solution of sodium thiosulphate for chlorin disinfectants or a similar dose of potassium sulphid for salts of the heavy metals.

Author's Combined Test-tube and Animal Bactericidal Method.—This method has proven serviceable for determining the bactericidal activity of disinfectants for such organisms as pneumococci, streptococci and anthrax bacilli virulent for white mice by intraperitoneal inoculation. It has the distinct advantage of controlling the result by animal inoculation, which in the case of a highly virulent culture of a pneumococcus constitutes in my experience a delicate test for viable microörganisms. The disadvantage of the test lies in the fact that in such a combined *in vitro-in vivo* method, some of the drug is injected intraperitoneally and probably continues its bactericidal activity within the peritoneal cavity for a short time at least.

In this method 1 c.c. of a dilution of the bactericide in serum, broth, or salt solution is allowed to act on 1 c.c. of a culture of pneumococci or other organism of known virulence so diluted that 0.1 c.c. contains 100 minimal lethal doses, at a temperature of 37°C.; at intervals of 5, 15, 30, 45, and 60 minutes, 0.2 .cc. of the mixture is injected intraperitoneally into mice to determine when killing of the pneumococci has occurred.

1. A twenty-four-hour broth culture of a pneumococcus or other organism is titrated by intraperitoneal injection into mice to determine the M.L.D. in a period of 24–36 hours after injection. This culture is then diluted with sterile broth until 100 times the M.L.D. is continued in each 0.1 c.c.

2. A dilution of the bactericide in serum, broth, or salt solution is prepared—for example, 1:1000 ethylhydrocuprein hydrochlorid—and 1 c.c. placed in a small sterile

tubule in a water-bath at 37°C. After a few minutes 1 c.c. of the diluted culture is added and the contents gently mixed. The dilution of bactericide has now been doubled (1:2000).

3. At intervals of 5, 15, 30, 45, and 60 minutes, 0.2 c.c. of the mixture is injected into the peritoneal cavities of white mice. The 1-c.c. graduated syringe used for this purpose is sterilized before each injection.

4. One or more controls are included by mixing 1 c.c. of the diluted culture with 1 c.c. of the same fluid used in preparing the dilution of disinfectant (serum, broth, or salt solution); the tubule or tubules are kept in the water bath and 0.2 c.c. injected into a series of mice at the same intervals.

5. The mice are kept under observation for at least six days, and at autopsy the blood of the heart is examined by smear and culture for organisms. During the first forty-eight hours death is generally due to bacteremia; after this time the blood is usually found sterile and death is ascribed to the toxicity of the drug injected.

Author's Methods for Determining the Bactericidal Activity of the Blood and Urine in Vitro, Following the Administration of a Disinfectant.—In the course of chemotherapeutic investigations it is sometimes useful to determine whether or not and for how long one may be able to detect an increased bactericidal activity of the blood or urine for a certain organism, presumably due to the presence of a chemical agent generally administered by intravenous injection. Various methods have been described from time to time and I have employed the following with considerable success and satisfaction.

As a general rule, experiments of this kind are conducted with rabbits because of the ease with which blood may be obtained from the veins of the ear. Large animals should be chosen and it is well to prepare one of the ears by shaving away the hair over the marginal veins. It is surprising, however, the frequency with which blood may be obtained without contamination by ordinary cleansing with soap and water followed by alcohol and ether. These manipulations usually render the marginal veins quite prominent and by pricking with a large sterile needle a good flow of blood is obtained. The various steps are as follows:

1. Prepare the ear as described. In each of a series of five small sterile test tubes marked off at the 5 c.c. level, place 4 c.c. of a sterile 0.2 per cent. solution of sodium citrate in saline. Collect 1 c.c. of blood in Tube No. 1.

2. Inject the compound by way of a vein in the opposite ear.

3. At chosen intervals like 5, 30 and 60 minutes collect 1 c.c. amounts of blood in Tubes 2, 3 and 4.

4. In the fifth or culture control tube place 4 c.c. of sterile broth.

5. Keep the five tubes in a water bath at 38°C. and in the meantime boil ten tubes of agar medium (10 c.c. in each) and cool to 45°C. Prepare ten sterile petri dishes.

6. Inoculate each tube with one 4 mm. loopful of a 24–48 hour broth culture of the chosen organism like *B. coli*, *staphylococcus aureus*, etc.

7. Mix well and 5 minutes later plate 0.05 c.c. of each mixture with 10 c.c. of agar at 45°C.

8. At the end of one or two hours prepare a second series of plates in the same manner.

9. After hardening incubate the plates upside down for twenty-four to forty-eight hours and count the colonies. The first or preliminary specimen of blood shows whether or not it is alone bactericidal but owing to the 1:5 dilution this is not usually the case even with typhoid and paratyphoid bacilli. The culture control plates usually contain a very large number of colonies and especially those poured at the end of one or two hours owing to proliferation of the organisms at 38°C.; if, however, the plates of post-administration blood prepared one or two hours after inoculation contain no more organisms than the plates prepared five minutes after inoculation, it may indicate that the blood contained bacteriostatic amounts of disinfectant.

The method is also suitable for measuring the bactericidal activity of the blood of human beings following the administration of optochin, mercurochrome and other substances in the treatment of disease. As a general rule, with rabbits only the maximum tolerated doses of such compounds as ethylhydrocuprein hydrochlorid show a distinct increased bactericidal activity of the blood for the pneumococcus, mercurochrome for *B. coli*, etc.

A second method which I have used with some success is an adaptation of the test devised by Heist, Cohen and Cohen[10] for measuring the bactericidal activity of whole coagulable blood. The essential feature of the method is that a capillary glass tube is filled, by capillary attraction, up to a fixed mark, with a broth culture of the bacterium, and then emptied. A certain number of bacteria remain sticking to the wall of the tube. Blood as it comes from capillary or vein is allowed to flow up the tube to the mark, and the tube is then sealed and incubated. If the blood has no bactericidal action the bacteria which have remained on the wall of the tube find themselves in a favorable medium and multiply rapidly; if it is bactericidal, they are killed and no growth results. Readings

are made by blowing out the contents of the tube on a glass slide, staining and examining it under the microscope. By combining several capillary tubes into one many-stemmed pipet, modeled after the one Wright uses for estimating the coagulation time of the blood, and by using a series of ascending dilutions of broth culture, an approximate quantitative value may be given to the test. Borow and myself[11] have employed this method with some success in measuring the bactericidal activity of the blood after the administration of ethylhydrocuprein hydrochlorid and I have described elsewhere[12] the details of the technic as well as the Stern and Korte plating and Wright capillary tube methods, all of which are likewise adaptable for measuring the bactericidal activity of the blood of human beings or the lower animals following the administration of disinfectant compounds.

Urine tests are best conducted with rabbits although it is very difficult to obtain uncontaminated specimens by catherization even under rigid aseptic conditions. The general plan of procedure is to catherize a male or female rabbit as carefully as possible to secure a control specimen of urine. The drug is then administered and at chosen intervals the animal is catherized for additional specimens. Each urine is then tested by placing 1 c.c. in a sterile test-tube in a water-bath at 38°C. and adding one 4 mm. loopful of a broth culture of the test organism (usually *B. coli* or a staphylococcus). An additional control should be included in which 1 c.c. of sterile water is used instead of urine. At the end of a chosen interval (usually 15 minutes) 4 c.c. of sterile water are added to each tube, mixed well, 0.05 c.c. transferred to a sterile petri dish and plated with 10 c.c. of agar at 45°C. After incubation for forty-eight hours the colonies are counted and the results evaluated in comparison with the controls.

Principles of Experimental Bacterial Infections in Relation to Chemotherapy.—But while bacteriostatic and bactericidal tests *in vitro* may be and usually are of distinct value in developing the chemotherapy of bacterial diseases, properly conducted *in vivo* tests employing systemic and localized experimental infections of the lower animals are usually the final tests for new compounds and if possible should be conducted before a substance is used or recommended for the treatment of diseases of human beings. It is true that experiments of this kind are usually very laborious and expensive and that it may be indeed difficult and even impossible to duplicate exactly the conditions occurring in the course of a disease in human beings for which the compound is designed but yet satisfactory experimental lesions can usually be produced with many of the pathogenic organisms for *in vivo* tests.

1. In my opinion, the first essential principle is to *avoid unnecessarily severe infections* because these may readily mask the feeble but definite curative effects of a compound under study. In serum and chemotherapeutic investigations in bacterial infections, animals are usually infected by subcutaneous or intraperitoneal injections of the test micro-organism resulting in the production of generalized infections associated with bacteremia and terminating fatally in a few days, or in a few weeks, as in experimental tuberculosis. As a general rule, the test animals are very susceptible to the test micro-parasite, and the results are evaluated by the duration of the lives of treated animals as compared with infected but untreated controls.

In experimental serum therapy of such bacterial infections as are produced by virulent pneumococci, streptococci, meningococci, anthrax bacilli, and so forth, this method is generally satisfactory because, owing to the low toxicity of the immune serums for the test animals, relatively large amounts may be given to influence favorably an otherwise rapidly fatal bacteremia and septicemia. But in chemotherapeutic studies in bacterial infections the *dosis curativa* of a medicament is likely to be but slightly less than the *dosis tolerata* or the *dosis lethalis*, and rapidly fatal and generalized infections do not disclose possible, although feeble, curative effects on the part of the compound under study, and thereby fail to yield information of value for the conduct of chemotherapeutic investigations.

For example, the maximum tolerated dose of ethylhydrocuprein hydrochlorid (optochin) for mice, by intravenous and intraperitoneal injection, is approximately from 20 to 40 mg. per kilo of body weight. When these animals are infected with 50 minimum lethal doses of Type I pneumococci, Cohen, Heist and myself[13] found that at least 20 mg. of drug per kilo must be administered at about the same time as the cocci to prolong the lives of approximately 20 per cent. of animals for an indefinite period. This amount was one half or more the highest tolerated dose and indicates the very small margin between *dosis tolerata* and *dosis curativa* of ethylhydrocuprein hydrochlorid for mice with pneumococcus bacteremia. Moore[14] has observed somewhat better results than we in the treatment of pneumococcus

bacteremia of mice with the ethylhydrocuprein base, but the margin between the toxic and curative doses was likewise small.

It is of course necessary to produce experimental lesions of such severity that untreated controls may not recover by natural means but we should carefully avoid producing overwhelmingly severe infections with rapidly fatal bacteremias.

2. A second principle is to *select an animal possessing some degree of natural resistance for the test organism.* For example, white mice are so susceptible to virulent pneumococci that it is very difficult to gauge a dose by intraperitoneal injection permitting the animal to survive for four or five days; white rats and guinea-pigs are more resistant and with a virulent culture may yield a longer experimental infection. Rabbits are so susceptible to virulent streptococci that a meningitis cannot be ordinarily produced of sufficient duration because of rapidly fatal bacteremia; cats and white rats are more resistant and offer much better chances for producing localized infections. In brief chemotherapeutic studies of bacterial infections demand that the infection shall not be too severe or too short in duration before a fatal issue. In the first place infections of human beings are rarely as severe as many of our experimental lesions and in the second place the toxic effects of the drug tends to still further depress resistance and favor the infection. We should aim, therefore, to conduct our experiments with animals possessing some degree of natural immunity for the test organism in order that there may be sufficient time to give several doses of the drug rather than to base results upon the administration of a single large dose which may actually shorten the lives of the animals as compared with untreated controls.

3. Indeed, I believe that this practically amounts to a third principle, namely, that *the infection shall permit of the administration of multiple doses of a drug* since there is but little hope for producing compounds capable of sterilizing completely in one dose, as arsphenamin and its allied compounds may accomplish in experimental trypanosomiasis and spirochetoses. Such may demand that we infect our animals with multiple small doses of organisms in order to produce a continuous, but milder infection ultimately fatal for untreated controls, and, indeed, during the past two years Dr. Harkins and I have developed a technic of this kind which has proven particularly serviceable for chemotherapeutic investigations of bacterial infections, as I shall shortly describe with more detail.

4. A fourth principle is to *give preference to the production of localized lesions rather than the production of almost immediate bacteremias.* For example, I believe it is much better to inoculate virulent streptococci into mice by subcutaneous injection as developed by Morgenroth, than by intraperitoneal injection. Bacteremia develops in addition to the local lesion, but it is less rapid, less severe and more closely duplicates the conditions of streptococcus infections of human beings. Pneumococcus infections are likewise produced by injecting the organisms directly into the lungs of mice, rats, guinea-pigs or rabbits and the resulting bacteremia is somewhat less severe. Anthrax bacilli may be injected subcutaneously rather than intraperitoneally, etc., the whole principle being to produce more or less localized lesions from which fatal systemic infections may spring as these are the usual events in bacterial diseases of human beings. It is true that in human beings some bacterial infections like typhoid fever, pneumonia, meningococcus meningitis, etc., may be bacteremias first with subsequent localizations; these conditions can hardly be duplicated in the lower animals but the final results are probably sufficiently well duplicated by producing local lesions first from which the blood becomes secondarily infected.

Chemotherapy of Experimental Localized Bacterial Infections of Serous Cavities.—Localized lesions of serous cavities also offer a special field of usefulness in chemotherapeutic research. Thus Sands and myself[15] have been able to produce well defined pneumococcus lesions by injecting intrapleurally 0.5 c.c. of twenty-four hour dextrose blood broth cultures of pneumococci of moderate virulence into the right pleural sacs of guinea pigs; as a general rule, this was followed by the development of acute suppurative plueritis on both sides with pericarditis. The lesions, however, were not strictly confined to the pleurae since both lungs frequently showed inflammatory changes and pneumococci were generally found in the blood. Extremely virulent cultures were unsatisfactory, inasmuch as rapidly fatal bacteremias ensued; cultures of moderate virulence in broth, rather than suspensions in saline solution, produced the best results, the broth probably aiding in the production of suppurative changes.

From our experiments it would appear that in experimental pneumococcus pleuritis sufficient ethylhydrocuprein hydrochlorid may be injected into the pleural sacs to render the contents decidedly pneumococcidal without

toxic effects, whereas the same amounts injected into the blood are without effect on the local lesions or pneumococcus bacteremia. Similar results have been observed by Idzumi and myself[16] in the treatment of experimental pneumococcus meningitis of rabbits with ethylhydrocuprein hydrochlorid.

In my opinion, the treatment of experimentally infected serous cavities and especially the pleural cavities, constitutes a procedure of distinct value in chemotherapeutic studies in bacterial infections when the curative dose of a compound is likely to be but slightly less than the maximum tolerated dose. In serum therapy or in chemotherapy with such arsenical compounds as arsphenamin in spirochetic or trypanosome (*Tr. equiperdum*) infections, when the curative amount is many times less than the toxic amount, generalized infections are suitable, since the compound may be given in relatively large doses without danger of poisoning.

Studies in the production of experimental tuberculous pleuritis by Ogawa and myself[17] have shown that it is possible to produce a tuberculous infection limited to the pleurae and lungs with such extension of the disease to the pericardium and lymph glands as occurs by direct lymphatic absorption and continuity of tissues. The intrapleural injection of guinea-pigs with bovine tubercle bacilli is followed by metastases to the spleen, liver, and other organs, that is, a generalized infection follows. Human tubercle bacilli likewise produce generalized infections but in not as high a percentage of animals. Human tubercle bacilli injected into the pleural cavities of adult rabbits generally (but not always) resulted in localized lesions; bovine bacilli regularly produced generalized lesions in these animals. Bovine and human tubercle bacilli injected into the pleural cavities of adult white rats and adult dogs have resulted in the production of localized lesions. By suspending the bacilli in broth instead of saline solution, the local suppurative changes generally have been increased. While extensive chemotherapeutic studies have not been made with these lesions, I believe that localized tuberculous pleuritis and pneumonitis offer more favorable lesions for studies *in vivo* than generalized and widespread lesions, the medicaments being injected into one or both pleural cavities at varying intervals after the injection of the bacilli into the right sac.

For the production of localized bacterial infections of serous cavities for purposes of chemotherapeutic research it would appear necessary to select test animals possessing some natural immunity for the test bacterium; furthermore, the bacterium should be of moderate rather than of extreme virulence. These factors decrease the chances of producing generalized infections and bacteremias and favor the development of localized lesions spreading only by direct continuity of tissues. Under these conditions subtoxic amounts of medicament injected into the cavities may produce therapeutic results even when diluted with inflammatory exudates and thereby yield information of value in chemotherapeutic investigations.

Value of Animal Experimentation in Relation to Bacterial Chemotherapy. This now logically brings us to the point where the advantages and limitations of chemotherapeutic investigations among the lower animals requires brief discussion. As stated in Chapter II, toxicity tests with new compounds are indispensable and especially when they are designed for administration by intravenous or intramuscular injection and even by ingestion; for purely local application to the skin or mucous membranes they may be dispensed with although even in this connection preliminary tests among the lower animals are advisable and especially when the medicament is to be used for instillation into the eye, urethra and bladder. Much too frequently new compounds are rushed into clinical use for the treatment of bacterial infec-

tions on the flimsiest sort of evidence of their probable value with few or no toxicity tests and with no data concerning their effects upon experimentally produced infections. It is true that antiseptics designed for local application cannot be easily tested on the lower animals, but all designed for the treatment of systemic infections should be first tested out by properly conducted animal tests.

Experiments of this kind will give at least some data bearing upon their effects in the treatment of an actual infection. When a new compound is found to be of relatively low toxicity and to possess an encouraging degree of bactericidal activity *in vitro* especially in a menstrum of serum or blood, it is a temptation to assume that it will prove efficacious *in vivo;* at least, it appears that such should be the case, but we know so little of the fate of chemical agents *in vivo* and of the fundamental laws of chemotherapy that we have no right to draw concusions or deductions until the compound has been actually tried out in experimental infections and this is usually possible. I do not mean to infer that a compound failing to favorably influence an experimental infection will prove worthless in the treatment of the corresponding disease of human beings, but experience has taught me that it is usually possible to make the animal test quite favorable for eliciting the possible curative properties of a chemical agent and that if it fails under these conditions, we should be extremely cautions in advising its use in the treatment of disease insofar as specific anti-bacterial properties are concerned, although it may possess certain pharmacological properties of general value aside from the purely chemotherapeutic applications.

The chief limitation of animal tests is the difficulty or impossibility of exactly duplicating the condition of the disease as it occurs in human beings and the tendency for making our tests unusually and unnecessarily severe. This is especially important when we remember that there is considerable data indicating that chemotherapy *in vivo* is probably not a mere matter of a disinfectant killing bacteria by direct action as it may in the test-tube but that certain synergistic tissue reactions may be required to bring about this result by more indirect means. Furthermore, the tissues of the lower animals may react in quite a different manner from those of human beings in this connection, as they are known to vary in reaction to some species of bacteria. The questions of chemistry of the blood and fixed tissues, natural immunity of the infecting organism and varying susceptibility to the toxic or organotropic effects of the compounds, are to be regarded as possible factors of variation and constituting limitations to the true value of animal tests for evaluating new compounds from the chemotherapeutic standpoint. But yet experience shows that, in a broad and general manner, animal tests may yield much more favorable results than observed in the treatment of human beings; at least, this is true in trypanosomiasis and syphilis and likewise in bacterial infections, as I shall discuss in Chapter VIII—devoted to the practical applications and results of chemotherapy in the bacterial diseases of human beings and the lower animals. Therefore, while it cannot be denied that compounds without demonstrable curative effects in experimental infections of the lower animals may be somewhat effective in human beings, yet it is a fact that the reverse of this is more common and indicating that we should always employ well conducted animal tests as part of our study of new chemical agents designed for the disinfection of tissues in systemic infections.

Various Methods for Chemotherapeutic Investigation in Experimental Bacterial and Mycotic Infections.—In this section I shall briefly summarize the more technical details for the production of various experimentally pro-

duced bacterial infections of the lower animals which have been found useful in chemotherapeutic investigations. It is obviously impossible to designate the exact amounts of organisms to employ as these vary greatly according to virulence, but the main principles of technic may be given. Needless to state all painful operations on the lower animals are to be conducted under anesthesia and with scrupulous care.

Methods for Chemotherapeutic Investigation in Experimental Tuberculosis.—Tuberculosis offers a particularly favorable infection for experimental chemotherapy because the duration of the disease may be prolonged over weeks or months without the production of acute overwhelming infections; this, however, may be also a disadvantage because of the long periods required for obtaining and evaluating the results of therapeutic experiments.

Local tuberculous lesions are readily produced in rabbits by inoculating the *cornea* or *anterior chamber of the eye* with virulent bacilli, preferably of the bovine type. My colleague, Dr. Harkins, has also produced *cutaneous* lesions by rubbing bovine bacilli into superficial abrasions of the skin of rabbits and by intradermal injections of very minute amounts of culture. After a few weeks, well-developed local lesions are produced which may be carefully watched and studied during treatment with drugs administered by intravenous or intraperitoneal injection or, in the case of the cutaneous lesions, by local application.

Ogawa and I[18] have also produced tuberculous *pleuritis* for the purpose of providing lesions for treatment with intrapleural and intravenous injections of drugs. In our work human and bovine strains of tubercle bacilli were inoculated into the right pleural cavities of rabbits, dogs, guinea-pigs and white rats. The distribution, type and severity of the experimental lesions varied considerably among the different species of animals and to some extent among the animals of the same species. As a general rule, the best developed lesions of the right pleura and lung were observed among animals having a certain degree of natural immunity to tubercle bacilli, such as the rabbit to human bacilli, the dog and rat to human and bovine bacilli.

Tuberculous *meningitis* may be produced by introducing the bacilli into the subarachanoid space. I have succeeded in infected dogs, rabbits and guinea-pigs by introducing the bacilli through a small trephine opening of the skull; successful inoculations have also been reported by intraspinal inoculations. In most of my experiments, however, distal lesions likewise developed in addition to progressive tuberculosis of the meninges.

Most experimental work in the chemotherapy of experimental tuberculosis has been conducted with *generalized infections* of guinea-pigs and calves inoculated by subcutaneous, intravenous or intraperitoneal injection of bovine bacilli. By careful selection of doses chronic and long continued, but progressive lesions may be produced admirably adapted for therapeutic tests.

The administration of drugs may begin any time after inoculation. Possibly the most favorable results are to be obtained by giving the first dose one or two days after inoculation to be followed by subsequent doses at chosen intervals, or the lesions may be allowed to develop before treatment is begun and thereby duplicate more closely the problems arising on the chemotherapy of tuberculosis of human beings involving the very important question of the penetrability of the drug for tubercles in various stages of formation and necrosis. For routine work guinea pigs inoculated with 0.1 to 0.01 mg. of bovine bacilli by subcutaneous injection may be used and treatment begun with two or more animals next day, with several others about three days later, others one week later, etc. The drug may be given by intravenous, intraperitoneal or subcutaneous injection at chosen intervals and in every experiment several untreated controls are to be included. The results are evaluated according to the duration of life and the progress of lesions, or necropsies may be conducted at a chosen time, as six weeks after inoculation, and the distribution and size of the lesions compared with those in the untreated controls.

Methods for Chemotherapeutic Investigation in Experimental Pneumococcus Infections.—Most investigation in the chemotherapy of pneumococcus infections have been conducted with mice according to the method in general use for determining the protective and curative activity of antipneumococcus serum.

In this method, *systemic or generalized infections* are produced by intraperitoneal or subcutaneous injection of mice with virulent pneumococci, the dose being based upon a preliminary virulence test. It is necessary to avoid overwhelming infections, the aim being to inoculate with a dose producing fatal bacteremia in four or five days; larger doses proving fatal in forty-eight hours are too severe and smaller doses may yield irregular results. My usual plan has been to determine the smallest lethal dose of an eighteen-hour blood dextrose broth culture in a period of five days and to inoculate for the main test with 10 to 50 times this amount. The drug may be injected intravenously, intraperitoneally or subcutaneously to some mice at the time of infection; others may be treated

two, four and twenty-four hours after inoculation. In each test several inoculated but untreated mice are to be included as well as two or more receiving the drug alone (controls). The results are usually evaluated according to the duration of life as compared with the untreated controls; a better way however, is to treat a series of mice with the same dose of compound and to express the results according to the percentage of survivals.

A second method, and one which I believe is to be preferred in some respects for the production of systemic infections, consists in giving a series of mice a daily subcutaneous injection of culture equal to the minimal fatal dose by intraperitoneal inoculation. The drug is also given daily by intraperitoneal injection 4 hours after each inoculation. Controls receive the culture alone and the drug alone in the usual manner. By this method acute overwhelming infections are avoided although fatal bacteremias are gradually produced in the untreated animals. If the controls do not show signs of infection by the third day the dose of culture may be increased at will and the experiment terminated when the untreated animals succumb; the results are expressed according to the smallest curative dose of compound per kilogram of weight.

These tests with mice may be modified by injecting the pneumococci directly into the lungs through the chest walls; small areas of pneumonia may be produced with bacteremia.

Rabbits may be employed instead of mice in the same kind of tests; guinea pigs and white rats, however, are more refractory, although I have used the latter as substitutes for mice with success by using highly virulent cultures.

Experimental *pneumonias* may be produced in dogs by introducing large amounts of culture directly into the trachea after the method of Wollstein and Meltzer;[19] rabbits may be used in the same manner according to the method described by Winternitz and Hirschfelder[20] or the culture may be injected directly into the trachea with a syringe or through a catheter introduced into the trachea by means of a small incision below the larynx. Monkeys, however, are probably best adapted for the production of pneumonias according to the methods developed by Blake and Cecil.[21]

Idzumi,[22] working in my laboratory, has produced *meningitis* in rabbits and dogs. The subthecal injection of virulent pneumococci into the lumbar region of the spinal cord of rabbits was usually followed by the development of a fatal suppurative leptomeningitis accompanied by definite changes in the tissues and spinal fluid, fever, leukocytosis and clinical symptoms of meningitis, such as hyperesthesia, opisthotonos and convulsions. These changes appeared to be sufficiently definite to permit the use of large rabbits for chemotherapeutic experiments in pneumococcus meningitis when they are infected by the direct subthecal injection of virulent pnuemococci. Meningitis may be produced in dogs by the subthecal injection of large amounts of highly virulent pneumococci; injections into the cisterna magna yield better lesions and have proven extremely valuable for chemotherapeutic studies in meningitis.

Sands and I[23] have also produced an experimental *pleuritis* in guinea-pigs by the injection of 1 c.c. of a twenty-four hour dextrose blood broth culture of virulent pneumococci into the right pleural cavity of guinea-pigs; acute suppurative pleuritis on both sides associated with suppurative paricarditis followed, which generally terminated fatally in three or four days with bacteremia. Chemotherapeutic experiments were conducted with optochin by direct intrapleural injection and offered new opportunities for the chemotherapeutic investigation of localized infections.

Methods for Chemotherapeutic Investigations in Experimental Streptococcus Infections.—Similar methods may be employed with streptococci due care being taken to work with a strain of high virulence maintained by occasional animal passage.

For *systemic infections* mice are well adapted for routine tests and especially when inoculated by injection under the skin of the thorax according to Morgenroth's method. Within forty-eight hours severe local lesions are produced characterized by extensive edema and containing myriads of organisms; the blood is gradually infected and streptococci are almost invariably found in the heart when cultured at necropsy. Preliminary virulence tests are required for determining the proper dose of culture to inject, the object being to use in the main tests a single dose capable of producing this lesion and proving fatal in about five to seven days.

Mice are now inoculated with this amount of culture. The drug may be given by intraperitoneal injection; sometimes the intravenous or subcutaneous routes are to be preferred. As a rule, I give the first dose of drug four hours after inoculation but one may lengthen this interval to twenty-four hours or longer when the local lesions are well under way. Subsequent doses are given at daily intervals. Untreated controls and controls receiving the drug alone are to be included in each experiment and the results evaluated according to the effects upon the local lesion, the duration of life and the cultures of the blood, as compared with the inoculated but untreated controls.

A modification of this test consists in giving the mice a daily injection of culture in about one tenth the single fatal dose. The drug is injected four hours after each inoculation and the injections continued until the inoculated but untreated controls have

succumbed, when the results are evaluated according to the size of the local lesions and duration of life among the treated animals. If one-tenth the minimal fatal dose fails to produce local lesions in the controls by the third or fourth day, the dose of culture should be raised. By this technic, it is sometimes possible to continue the experiment for ten days or longer and the milder, but continuous infection more closely resembles the conditions of streptococcus infections among human beings and affords a more favorable lesion for eliciting the possible curative effects of compounds than the acute overwhelming infections following inoculation with single large doses of culture.

Rabbits may be employed in much the same manner and are particularly serviceable when it is desired to give repeated doses of the drug by intravenous injection. The method of daily subcutaneous injections of streptococci followed two to six hours later by the administration of the drug is a particularly good one and the dose of culture may be increased or decreased according to the condition of the untreated controls.

Rats and guinea-pigs are much more resistant to streptococci but may be employed if a highly virulent culture is available; I have repeatedly used the white rat with satisfactory results.

Streptococcus *pneumonia* and *empyema* has been produced in dogs by Wollstein and Meltzer,[24] and likewise by Graham and Bell,[25] by means of intrabronchial insufflation of cultures or empyema fluid. Gay and Rhodes[26] have employed rabbits infected by intrabronchial insufflation with 1 to 10 c.c. of a passage culture of hemolytic streptococcus. Histologically, this pneumonia was lobular in distribution, necrotizing in effect, did not resolve readily, and was characterized by peribronchial and perivascular edema and later infiltration of mononuclear cells (interstitial bronchopneumonia). It was quite different in character from the pneumonia produced by the pneumococcus. These differences were further marked by the occurrence of pleurisy with effusion, involving by extension both pleural cavities and the pericardium. Bacteremia occurred only irregularly.

Within the past year, Miss Rule and I have produced streptococcus *meningitis* for chemotherapeutic studies in this disease with a virulent hemolytic strain introduced into the subarachanoid space. Rabbits were found unsuitable because of early death due to bacteremia. Rats and guinea-pigs being more resistant were found more satisfactory and especially white rats of 200 to 300 grains inoculated through a small trephine opening near the middle line of the calvarium. Cats and especially dogs are also suitable and these may be infected by intralumbar or intracisternal injection. The dose of culture to employ must be determined in preliminary tests and dilutions may be made with sterile broth instead of saline solution as this aids in producing a more extensive exudation of leucocytes. Drugs are given by intravenous or intracisternal injection or through the same trephine opening employed for inoculation. It is a comparatively easy matter to produce acute meningitis by these means with purulent cerebrospinal fluids containing enormous numbers of streptococci.

Methods for Chemotherapeutic Investigation in Experimental Staphylococcus Infections.—Since most of the lower animals possess a high natural immunity to staphylococci it is more difficult to conduct chemotherapeutic investigations with these organisms. Rabbits, however, may be injected intravenously with *Staphylococcus aureus* in sufficient amounts to produce abscesses in the kidneys, heart, diaphragm, etc. As a general rule, preliminary tests are required for the purpose of determining how much of a twenty-four hour broth culture injected intravenously is required for producing these lesions of the internal organs. In the main tests each animal may be given this dose of culture to be followed four hours later by the first dose of drug with daily injections thereafter for about a week or ten days, when all surviving animals should be necropsied and the extent of involvement among the treated animals compared with the untreated controls. A better method, however, is to give a daily injection of culture in smaller dose followed by a daily dose of drug four to six hours after each inoculation. Controls receiving the cocci alone and drug alone should be included. By gradually raising the dose of culture, it is possible to produce fatal infections in the untreated controls within a week to ten days, but as a general rule it is required to terminate the experiment arbitrarily at about this time and evaluate the results on the basis of macroscopic and microscopic examination of the kidneys, heart and other organs of the untreated controls as compared with the treated animals.

I have also produced satisfactory lesions in the white rat by injecting virulent staphylocci intravenously in a single large dose found sufficient in preliminary tests for producing abscesses in the kidneys as determined by necropsy examination five to seven days later. The drug may be given intravenously or intraperitoneally either in a single large or multiple small doses, the first dose being given in two to twenty four hours after inoculation and before the infection has made too much headway. Cultures of the heart blood in both rabbits and rats have sometimes showed that bacteremia may develop but the animals do not succumb as rapidly or as regularly as with pneumococcus and streptococcus infections.

Virulent staphylococci may be injected subcutaneously in rabbits with the production of local abscesses, but in my experience bacteremias and abscesses of the kidneys and other internal organs have developed only exceptionally and irregularly.

Methods for Chemotherapeutic Investigations in Experimental Anthrax Infections.—White mice and rabbits are commonly employed for chemotherapeutic studies in anthrax; both animals, however, are very susceptible and if a highly virulent culture is employed amounts almost unbelievably small may suffice for producing rapidly fatal bacteremias. My colleague, Dr. Harkins, has observed that mice inoculated subcutaneously with a dose so small that cultures prove sterile, like 0.00000001 c.c., may produce a fatal infection; in other words this may mean a single bacillus or spore unable to proliferate in an artificial culture medium but yet capable of rapidly infecting a mouse. It is necessary, therefore, to first determine the virulence of a culture for mice or rabbits by injecting various amounts subcutaneously and choosing for the main tests an amount about ten times higher than the minimal fatal dose at the end of five to seven days. Subcutaneous edema usually follows and at death anthrax bacilli are to be found in the blood of the heart by smear and culture and in the liver, spleen and other organs by histological examination.

The drug may be given intraperitoneally to mice and intravenously to rabbits. It is generally advisable to give the first dose in two to four hours after inoculation and to follow this by daily injections. The usual culture and drug controls should be included and the results evaluated according to the duration of life or percentage of survivals among the treated animals.

With rabbits it is possible to adopt the method of giving a daily subcutaneous injection of culture followed in four hours by a daily injection of the drug. In this manner milder and more prolonged infections may be produced somewhat more favorable for eliciting the possible curative properties of the drug under study.

Methods for Chemotherapeutic Investigations in Experimental B. Coli and Typhoid Infections.—The experimental production of *B. coli* and *B. typhosus* infections among the lower animals have not been very successful. It is true that the daily intravenous inoculation of rabbits with *B. coli* or *B. typhosus* may produce fever and wasting with cloudy swelling of the kidneys, but local lesions comparable to those occurring among human beings are not produced, the effects being due to the toxins of the organisms. *B. coli* infections are of interest mainly from the standpoint of the experimental production pyelitis and cystitis and the possibility of influencing these therapeutically by the administration of such compounds a hexamethylamin and hexy-resorcinal.

I have been occasionally successful in infecting the bladders of female rabbits by repeated direct inoculation with cultures of *B. coli* freshly isolated from human infections, but in no instance so far has a pyelitis followed and the cystitis has tended to heal and disappear spontaneously. It is possible, however, to experiment along these lines in conjunction with tests for an increased bactericidal activity of the urine as previously described. By infecting the bladder with the introduction of 1 or 2 c.c. of a twenty-four-hour broth culture followed in about four hours by the administration of the drug and 30 to 50 c.c. of water by the stomach tube, it is possible to study the bactericidal effects of the drug in the bladder by removing specimens of urine as aseptically as possible at subsequent intervals. In my experience female rabbits are to be preferred but male rabbits may be employed although it is extremely difficult to secure urine without contamination.

A complete review of attempts to produce experimental typhoid infections among the lower animals has been given by Gay;[27] with the exception of a few successful results with apes these experiments have usually failed to reproduce the lesions commonly found in human beings. Gay and Claypoole,[28] however, believe that it is possible to produce a carrier state in rabbits which may prove useful for chemotherapeutic investigations.

Methods for Chemotherapeutic Investigations in Experimental Mycotic Infections.—It is possible to transmit some of the mycotic infections and especially the ring-worms to the lower animals and produce lesions well adapted for chemotherapeutic experiments by the local application or systemic administration of drugs. Young guinea-pigs are especially suitable, the abdomen being shaved and the organisms inoculated into superficial abrasions in two different areas, one area being reserved for control purposes when cutaneous applications of compounds are made. The shaven ears of rabbits may be likewise employed.

CHAPTER V

ANILIN DYES IN THE CHEMOTHERAPY OF BACTERIAL DISEASES

As stated in Chapter III in the historical review of chemotherapeutic investigations in bacterial diseases, the anilin dyes have long held a place of primary interest and importance, not only from the standpoint of displaying a direct bactericidal activity themselves, but also as possible carriers of more potent substances to the protoplasm of the organisms. While we now know that mere staining of bacteria does not necessarily indicate their death, yet the idea and hope of utilizing dyestuffs for the disinfection of the tissues have been long entertained and interest in the subject greatly renewed within recent years. Naturally a very extensive literature has accumulated upon the subject and especially upon the bacteriostatic and bactericidal activity of the dyes *in vitro*, but unfortunately most of these reports can be reviewed only in a broad and general manner, because the methods employed have varied greatly and the influence of technic upon the results is so tremendous that fine distinctions and deductions cannot be drawn.

Classification of Dyes in Relation to Chemotherapy.—Practically only the synthetic dyestuffs prepared from coal tar have been employed for the staining of bacteria and for bacteriostatic and bactericidal purposes. Natural dyes, like Indian-yellow, quercetin, chrysin, cochineal, carmine, cudbear, hydrastis, etc., have been proven to be without parasiticidal properties and have not been employed for these purposes.

A very large number of dyes have been prepared from coal tar and their chemistry is exceedingly involved, the exact constitution of not a few being still in dispute and their preparation kept as trade secrets. Furthermore, the various dyes available are not always in a pure state and sometimes vary greatly in their staining properties, toxicity, bacteriostatic and bactericidal activity.

The large number of organic dyestuffs which have been synthetically prepared show that the dyeing property is dependent upon structure and a

theoretical classification has been based according to the chromophore group occurring in them; a very useful description of the chemistry of those employed in the textile industries is given by Cain and Thorpe.[1] The following classification is after that given by them and in each group I have included some of the dyes which have been employed in bacteriological work and to a more or less extent in experimental chemotherapeutic investigations:

(1) The *nitroso-dyes*, or nitroso-phenols produced by the action of nitrous acid on the phenols, and embracing such dyes as fast or solid green, naphthol-green B, gambine Y, etc.

(2) The *nitro-dyes*, produced by the introduction of the nitro group into the molecule of the aromatic phenols, and including picric acid, martius-yellow, naphthol-yellow S, etc.

(3) The *azo-dyes*, constituting an important group including such well known dyes as trypan-blue and trypan-red, prepared by the interaction of a diazo-salt with an aromatic hydroxy-compound or amin, and embracing such amidoazo dyes as acid-yellow, chrysoidin, sulphon acid-blue R; oxyazo-dyes, as ponceau-fast red, buffalo-fast crimson R, Columbia-blue R and a host of others; diazo-dyes as benzo-azurin, palatine black, resorcin-brown, sudan III, diamond-green, brilliant crocein M, etc. Belonging to this same group are also the dyes from tetrazo-salts like Congo-red, benzopurpurin B, diamin fast-red F, etc.; such triazo-dyes as Columbia-green A, benzo-fast blue B, direct black V, and such tetrakisazo-dyes as benzo-brown G, hessian brown BB, dianil-black PR, etc.

(4) The *triphenylmethane dyes*, probably the most important group of all from the standpoint of chemotherapy, generally considered as anhydro derivatives of triphenyl-carbinal, and including such dyes as basic fuchsin, acid fuchsin, parafuchsin, gentian-violet, magenta, hexamethyl-violet, hexaethyl-violet, methyl-green, Victoria-blue, nightblue, Dobner's violet, malachite green, brilliant green, acid-green, glacier-blue, setoglaucin, setocyanin, water-blue B, new fast green, etc.

(5) The *diphenylamin dyes* also include several of special interest from the standpoint of chemotherapy, embracing the indophenols, thiazins, oxazines, indamines and azures and including such dyes as methylene-blue, thiopyronin, toluylene-red, safranin, Bundschedler-green, nile blue By, neutral red, etc.

(6) The *acridin dyes*, which are amido derivatives of phenylacridin and of acridin base and including acriflavin, proflavin and a new compound 2-aethoxy-6, 9-diamino-acridin-chlorhydrate prepared by Morgenroth, Schnitzer and Rosenberg[2] and known under the trade name of "rivanol." Acriflavin is the name given to "trypaflavin" by the Medical Research Committee of Great Britain because the latter was a registered trade mark; the compound was first prepared by Benda[3] at Ehrlich's instigation in 1911, and was found to have such a marked therapeutic effect in trypanosomiasis that the name "trypa-flavin" was given to it. Proflavin is another acridin derivative, diaminoacridin, and appears to be easier and cheaper to manufacture and about equal in bactericidal activity but of lesser toxicity. Probably acriflavin has commanded more attention than any other dye and especially since it is apparently non-injurious to the tissues, diffuses readily in them and possesses other properties of value in the treatment of wounds. It may not be amiss to state here that the names of various other compounds ending in "flavin" are of commercial appellation and have no scientific generic basis, the "flavins" being yellow dyes. Acriflavin connotes a yellow derivative of acridin; thioflavin means a yellow substance containing sulphur. Other "flavins" have names coined in the same manner.

(7) The *pyronin dyes* including both diphenylmethane and triphenylmethane derivatives, like pyronin G, acridin-red, fluorescein and its sodium salt (uranin), fast acid-violets, fast acid-blue, the eosins, etc.

(8) Dyes of the *auramin* series, quinolins like cyanin B and indigoid colors like scarlet 6R, have been much less frequently employed.

Bacteriostatic and Bactericidal Activity of the Synthetic Dyes in Relation to Chemotherapy.—The synthetic dyes vary greatly in bacteriostatic and bactericidal activity. Some dyes, and especially certain members of the triphenylmethane and acridin series, like gentian-violet, acid and basic fuchsin, brilliant green, acriflavin, proflavin and rivanol, are very highly bactericidal, while others like methylene-blue and fluorescein are relatively feeble and mainly employed in chemotherapy for the purpose of combination with mercury or some other more highly bactericidal substances for aiding penetrability. Gentian-violet and magenta may inhibit the growth of staphylococci and streptococci in culture media in dilutions as high as 1:1,000,000 and 1:100,000 dilutions in agar or egg medium and are commonly

employed for aiding in the isolation of tubercle bacilli and organisms of the typhoid-colon group.

As a general rule, however, the majority of anilin dyes are relatively feeble in bactericidal activity and especially in the presence of serum, blood, pus and other organic matters. Probably gentian-violet, acid fuchsin, brilliant green and acriflavin possess the highest bacteriostatic and bactericidal properties, gentian-violet being particularly destructive for Gram-positive bacteria and the fuchsins for Gram-negative bacilli. Even dyes of the same series vary greatly in these properties, to which further reference will be made shortly when discussing selective activities; here it may be stated that while many of these dyes are sufficiently bacteriostatic and bactericidal *in vitro* to be of great aid in the isolation of some organisms, some are relatively feeble in the chemical disinfection of the tissues by local or topical application or by intravenous injection.

Bactericidal Activity of the Dyes in Vitro.—Gay and Morrison,[4] in a recent study of the bactericidal properties of a large number of dyes, have observed that in a general way both streptococcus and staphylococcus are more susceptible to dye-stuffs, with few exceptions, than is *B. typhosus*. Generally speaking, the streptococcus studied was more susceptible than the strain of staphylococcus. It would seem from their experiments that diazo dyes have relatively little bactericidal properties and that the most active dyes for streptococcus belonged to the triphenylmethane and acridin groups.

My own observations, however, have not shown as high bactericidal effects on the part of a number of anilin dyes for these three organisms as observed by Gay and Morrison. The technic employed, however, was radically different since the exposure allowed for the action of the dyes on the organisms was only five minutes and affords additional proof of the statement that the dyes act rather slowly. For example, gentian-violet in saline solution was completely bactericidal for a streptococcus in only 1:1000 to 1:1500 in this exposure, while for a culture of *Staphylococcus aureus* the bactericidal dilution varied from 1:2000 to 1:2400. Krigler[5] has shown the marked influence of the composition and reaction of the medium upon the behavior of the dyes *in vitro* and has employed a peptone medium with a pH of 7.1 in testing a large number of organic substances including many of the dyes, against various Gram-negative and -positive organisms. Norton and Davis[6] have also used a number of the dyes incorporated in culture media in attempts to work out a method for differentiating *streptococcus viridans* from pneumococci, but without success. Acid dyes or salts of acid or basic dyes were found to be practically inert; in their opinion a dye to possess bacteriostatic action must contain three benzol rings and two or more amino-groups in which the hydrogen atoms have been substituted by alkyl radicles.

The dyes have also been studied in relation to bactericidal activity *in vitro* for the *tubercle bacillus*, some of the earliest chemotherapeutic experiments in tuberculosis being made with these substances. Lewis,[7] with the assistance of Kraus, found that many of the triphenylmethane dyes as a group were more bacteriostatic and bactericidal for the pneumococcus and *Staphylococcus aureus* than for the tubercle bacillus, while the azo-dyes as a group inhibited the growth of tubercle bacilli more readily than these other organisms. Unfortunately, however, trypan-red and trypan-blue, which are capable of penetrating to the centers of fully formed tubercles in rabbits and guinea-pigs within a few hours after injection, have been found by DeWitt[8] and others almost without bactericidal power for tubercle bacilli both in the test tube and in infected animals. Lewis, DeWitt and others have prepared many new compounds of trypan-red and trypan-blue with iodin, phenol and the metals and while bactericidal activities *in vitro* were sometimes increased, unfortunately penetrability for tubercles was usually lost, so that the results of treatment of infected animals were largely negative. The same was largely true of new compounds of Niagra-blue with iodin, phenol and certain fatty acids. One compound of the dye with formic acid showed a great increase of bacteriostatic power *in vitro* without loss of power to stain the tuberculous tissues. Of several diazo-creosote combinations, one violet blue in color, inhibited the growth of tubercle bacilli in dilution as high as 1:100,000 and appeared to extend the lives of a few treated animals.

Because of the unusual fat content of tubercle bacilli, it was early thought that fat soluble and fat staining dyes might have a special action on tubercle bacilli, but Corper[9] has found no inhibitory action of fat dyes on the growth of tubercle bacilli, no power to penetrate living tubercles and no therapeutic effect in experimental tuberculosis of guinea-pigs.

Probably methylene-blue and its various combinations have been more extensively studied in tuberculosis than any other dye. DeWitt[10] has found that 1:10,000 dilutions

may prove bacteriostatic *in vitro* and bactericidal in some cases in 1:100 solutions though weaker solutions were not tried. Animals inoculated with bacilli previously exposed to 1:100 solutions usually developed a milder infection with a longer period of incubation, but the dye and a large number of combinations, yielded almost negative results in the treatment of tuberculous guinea-pigs, which subject I will review shortly in a more detailed discussion of the action of the dyes *in vivo*.

Of great importance in relation to the chemotherapy of infected wounds and various localized infections of the skin, mucous membranes and serous cavities, is the question of bactericidal activity in the presence of blood, serum and pus. Browning and Gulbranson[11] in 1917 discovered that the bactericidal activity of acriflavin is apparently enhanced by admixture with serum, though greatly diminished by pus. Hewlett,[12] Dakin and Dunham,[13] Drummond and McKee[14] and others have observed essentially similar results in serum and defibrinated blood, not only with acriflavin, but with proflavin as well; others, however, like Morgan,[15] Mueller[16] and Graham-Smith[17] have not arrived at similar conclusions. Gay and Morrison, working with a pus produced experimentally by the intrapleural injection of rabbits with virulent streptococci, found that most of the dyes studied lost markedly in bactericidal power in the presence of pus. A considerable number remained rather active and a few of them like safranin, methylene-green, basic fuchsin, rhodulin-violet and two flavin compounds were as active in pus as in broth; acriflavin was actually more active in pus than in broth.

Curiously the bactericidal activity of gentian-violet is reduced much more markedly by blood than by serum. I have observed, for example, that in a mixture of 4 c.c. of broth plus 0.5 c.c. of a culture of *streptococcus* and 0.5 c.c. of 1:100 gentian-violet (final concentration 1:1000), that complete sterilization occurs in a minute or less; similar results occurred when sterile serum was used instead of broth, but when whole citrated human blood was employed, complete sterilization did not occur in even an hour. Identical results were observed with a culture of *Staphylococcus aureus*.

From the standpoint of the treatment of infected wounds and various infections of the skin, mucous membranes and serous cavities or of systemic infections by intravenous injection, the anilin dyes are relatively feeble and their choice narrowed down largely to acriflavin, proflavin, gentian-violet, acid and basic fuchsin and possibly malachite green. This subject however, will shortly receive further consideration from the standpoint of their value in the actual treatment of localized and systemic infections.

Bactericidal Activity of the Dyes in the Blood and Urine in Vivo.—Of great interest and importance in relation to the chemotherapy of bacteremia is the question of bactericidal activity and fate of the dyes when introduced into the blood, usually by intravenous injection. This has been studied by injecting the dyes and withdrawing blood at intervals for bactericidal tests and also by producing experimental bacteremias of rabbits and treating with intravenous injections of the dyes. In 1913, Churchman and Herz[18] reported that the intravenous injection of a rabbit with 10 c.c. of a 1:200 solution of gentian-violet (0.05 gm.), corresponding roughly to the rather large dose of approximately 0.025 gm. per kilogram of weight, was followed by a loss of selective bactericidal activity of the blood about one hour later. Evidently this is due to its removal from the blood by the fixed tissues since further experiments consisting in the addition of the dye to blood *in vitro* showed no loss or reduction in selective bactericidal effects. Churchman[19] also states that he has not been able to kill organisms circulating in the blood by intravascular injections of gentian-violet, but I will later refer to this subject in a discussion of the use of the dyes in the treatment of experimental bacterial infections. Browning and Gulbranson state that intravenous injections of acriflavin temporarily increase the bactericidal effects of the blood, but I have found that these effects for streptococci disappear within an hour after the injection of rabbits with 0.010 gm. per kilogram of weight.

It would appear, therefore, that large doses of gentian-violet and acriflavin injected intravenously may at least temporarily increase the bactericidal activity of the blood (for about an hour), but these effects may not be sufficient for materially influencing a severe experimentally produced bacteremia since the dyes are rapidly absorbed by the tissues but, the bactericidal effects may be better in the less severe bacteremias of human beings.

Of further interest in this connection, and especially in relation to the treatment of bacterial infections of the kidneys and bladder, are the observations of Young and Hill[20] who found that the urine of rabbits removed aseptically by catherization following the intravenous injection of 0.005 to 0.010 gm. of gentian-violet per kilogram of weight was bacteriostatic and bactericidal for staphylococci and the colon bacillus.

Bactericidal Activity of Mixtures of the Dyes.—The question of the bactericidal activity of mixtures of various dyes deserves brief consideration. Gay and Morrison have tested various combinations for streptococci, staphylococci and typhoid bacilli and found that the final bactericidal dilution of such mixtures might reach the limit of the stronger dye, but in case of interaction and precipitation between the two solutions the bactericidal effect was actually decreased. Churchman[21] has observed that mixtures of gentian-violet and neutral acriflavin are bactericidal; also mixtures of gentian-violet and fuchsin, the gentian-violet for Gram-positive organisms and the acriflavin and fuchsin for Gram-negative organisms. In my experiments these observations have been confirmed and in the mixtures the identity of the dyes appear to be well preserved in that the bactericidal effects of the mixture for Gram-positive organisms is approximately the same as shown by the gentian-violet alone in the same strength and the bactericidal effect for Gram-negative organisms being about the same as shown by the acriflavin or fuchsin alone in the same strength. Churchman has advocated, therefore, the use of mixtures of these kinds for the disinfection of tissues infected with both Gram-positive and -negative organisms, to which further reference will be made in a succeeding chapter.

Influence of Heat upon the Bactericidal Activity of the Anilin Dyes.—Since heat tends to increase the rapidity and rate of chemical reactions, it is to be expected that hot solutions of the anilin dyes will prove more bacteriostatic and bactericidal than cold solutions and Churchman[22] has furnished definite proof that moderate heating (55°C. for 1 hour or 50°C. for 1½ hours) increases the penetrative power and bactericidal activity of gentian-violet. Working with an impeccable gentian-violet-fast strain, he found gentian-violet without effect at 22° to 35°C., but bactericidal when the solution of dye was heated to 50°C.; control tests showed that the effects were not due to heat alone or the dye alone, but to the combination of heat plus dye. The phenomenon has not been explained but the facts established indicate that when the dyes are used for the treatment of localized infections by direct application, the solutions should be comfortably hot in order to secure the enhanced bactericidal effects.

Selective Bacteriostatic and Bactericidal Activity of the Anilin Dyes in Relation to Chemotherapy.—As would be expected, the anilin dyes vary greatly in bactericidal activity and, as shown above, may exert a stronger bacteriostatic and bactericidal activity for some organisms than for others. Most of the anilin dyes in high concentration, say 1:100, will kill practically all organisms irrespective of whether they are cocci or bacilli, Gram-positive or Gram-negative, spore formers or non-spore formers, virulent or non-virulent, but some of them show bactericidal and bacteriostatic properties for some organisms in concentrations without effect upon other organisms. This is designated as "selective activity" and bears a very intimate relationship to chemotherapy, since it appears that the chemical constitution of the molecule influences these specific properties.

This selective bacteriostatic and bactericidal activity of the anilin dyes, first pointed out by Rozsahegyi[23] in 1887, the literature being fully described by Simon and Wood,[24] has long been utilized for aiding in the isolation of bacteria in cultures, as first shown by Drigalski and Conradi in their well-known medium employing crystal-violet for the isolation of typhoid bacilli from the feces. Since then a large number of special media have been

advocated on the principle of incorporating an anilin dye for the purpose of restraining certain bacteria while allowing others to grow.

Churchman[25] has especially contributed a most valuable series of studies bearing upon this important topic of selective activity of the dyes. He has clearly proved that gentian-violet, magenta and other dyes of the triphenylmethane series in general, possess a selective bacteriostatic and bactericidal activity for the Gram-positive organisms and especially the spore formers, arbitrarily designated as "normal activity;" curiously enough, however, these dyes may not inhibit the growth of the Gram-positive tubercle bacillus, a fact utilized by Petroff in the preparation of his valuable egg medium for the isolation of these organisms. While Churchman originally believed that the bacteriostatic activity of gentian-violet closely followed the Gram reaction, that is, was effective against Gram-positive organisms but not against *B. coli* and other Gram-negative bacilli, he has more recently[26] discovered that the process is not so specific, since he found in a culture of the colon bacillus two different strains, one which was restrained by gentian-violet and one which was not; Churchman has designated this as "microbic dissociation" and the discovery indicates how involved and complicated is this subject of the selective activity of the dyes.

Furthermore, dyes belonging to the same series may show opposite effects. For example, acid and basic fuchsins also belong to the triphenylmethane dyes, but yet, as shown by Churchman,[27] these restrain and kill Gram-negative organisms like *B. coli*, *B. pyocyaneus*, etc., designated as "reverse selective activity," whereas gentian-violet kills the Gram-positives like *B. diphtheriae*, *B. anthracis*, the staphylococci, streptococci, etc. In other words, such closely related dyes as basic triphenylmethanes (magenta) differ in bacteriostatic power from acid triphenylmethanes (the sulphonated compound acid fuchsin), since the former is more active than the latter. I will shortly discuss the matter of chemical constitution in relation to this phenomenon, but these discoveries by Churchman have shown to what extremes the selective activity of the anilin dyes may reach. This "reverse selective activity" of the anilin dyes has enabled Churchman[28] to isolate organisms in pure culture, as mixtures of *B. pyocyaneus* (Gram-negative) and *B. megatherium* (Gram-positive), by the use of these two dyes.

But the phenomenon of "reverse selective activity" on the part of some of the anilin dyes is also influenced by the medium in which they are incorporated. I have already discussed above the observation that the bactericidal activity of practically all of these dyes is reduced in the presence of serum, pus and blood, the acridin dyes like acriflavin, proflavin and rivanol being noteworthy exceptions; but Churchman[29] has shown that, while gentian-violet inhibits the Gram-positives and spares the Gram-negatives, acid fuchsin, related sulfonic substances, acriflavin and proflavin act in a different manner. When these are added to the agar (extrinsic bacteriostatis), the Gram-positive spore bearers are inhibited and the Gram-negatives unaffected; when added directly to the bacteria (intrinsic bacteriostasis) followed by transplanting the stained bacteria to agar, exactly opposite effects are noted since the Gram-negatives were inhibited and the Gram-positive spore bearers unaffected.

Churchman[30] has also shown that gentian-violet possesses a selective activity in the staining of bacteria and tissue cells, since the dye may penetrate and stain the nuclei of cells without destroying them while Gram-positive bacteria are killed; he has utilized this discovery in the treatment of arthritis and other localized infections. The use of brilliant green for the destruction of *B. diphtheriae* in carriers, of acriflavin for the removal of menin-

gococci in carriers, of various dyes in the treatment of urethritis, conjunctivitis, etc., are based upon this difference in toxicity for tissue cells and organisms. But in the opinion of Burke and Skinner[31] the selective bactericidal action of the triphenylmethane dyes applies only to the vegetative forms since the spores are highly resistant.

The list of examples of selective bacteriostasis and bactericidal activities of these dyes by Shiga,[32] Browning and Gilmour[33] and others may be extended to greater length, but without particular profit, since we are here mainly interested in the principles involved in relation to chemotherapy. But the subject is of great importance in relation to the chemotherapy of bacterial infections, since knowledge already gained indicates that when a dye is to be used for the treatment of a localized infection, it should be selected on the basis of greatest bacteriostatic and bactericidal activity in pus for the particular kind of organism present; at least to the extent of selecting gentian-violet for Gram-positive and acid fuchsin or acriflavin for Gram-negative bacteria. Furthermore, if new compounds of the dyes are to be synthesized, like compounds with mercury, copper, silver, etc., the selection of the dye should be influenced according to the particular group of organisms for which the compound is intended in order that the bactericidal activity of the compound may be enhanced by the intrinsic bactericidal activity of the dye. It is possible that mercurochrome prepared with a triphenylmethane dye, instead of fluorescein, may be improved upon in this manner, although I hasten to add that the subject is by no means as simple as it reads since the chemical manipulations may greatly reduce the bactericidal activity of the dye, as I well know from experience in the synthesizing of compounds of the anilin dyes with the more highly bactericidal heavy metals.

Chemistry of the Anilin Dyes in Relation to Chemotherapy.—Unfortunately, but little may be written at the present time upon this very important subject of the relation of chemical constitution of the anilin dyes to their bacteriostatic and bactericidal activities. Experts in the dyeing industries have worked out certain laws governing the dyeing of fabrics in relation to chemical constitution of both dye and fabric, but our information in relation to the bacteria is very meagre. It is practically certain, however, as shown by Churchman and others, that staining or dyeing of living bacterial cells does not necessarily kill them and that the bactericidal portion of a dye may be indeed a colorless portion, these observations indicating that the relation between chemical constitution and disinfection is much more complicated than between chemical constitution and mere protoplasmic staining.

But some information has been gained in this important subject. Browning and Gilmour,[34] for example, working with the *triamidotriphenylmethane* group of dyes observed that the unsubstituted triphenylmethane compound (pararosanilin) has only a comparatively weak bactericidal action. The substitution of alkyl-groups in the amido-side-chains (hexamethyl- and hexaethyl-violet) leads to the most active bactericidal substances known for staphylococcus, as originally shown by Dreyer, Kriegler and Walker[35] with methyl-violet, *B. anthracis* and *B. diphtheriae*. Morgenroth and his colleagues[36] have been especially interested in the chemical constitution of the acridin dyes in relation to bactericidal activity for streptococci and in tests employing serum-broth dilutions of these dyes found that the structure of the whole molecule may influence the function of the side arms, but that in the acridins the alkyl groups are the most active therapeutically and the isoamyl groups the least. As a result of these investigations "rivanol" (2-aethoxy-6, 9-diaminoacridin chlorhyrate) was evolved and found particularly effective in the treatment of mice inoculated subcutaneously with virulent streptococci.

Working with gentian-violet and magenta as "normal" triphenylmethanes and with acid fuchsin and the trisulfonic acid salt of rosanilin as representatives of "reverse selective activity," Churchman[37] has shown that the selective activity of these dyes is not to be ascribed to sodium. On the contrary however, the presence of SO_3 radicals appears to account for reverse selective activity. It would appear, therefore, as stated by Churchman, that with this group of dyes at least, the specific selective activity might "depend not so much on the presence of the sulfonic group as on the method of its bonding, though it is exhibited by substances like chromotropic acid, in which the SO_3 group is firmly attached, as well as by substances like sulfonic acid, in which the bonding is very weak. It is, however, well known that physical chemists are moving away from the ready explanation of phenomena of this sort on a purely chemical basis and are tending more and more to regard them as physical in nature."

Krigler,[38] whose work has already been referred to and the results of which also showed marked selective activities on the part of various organic compounds including some of the dyes, has also drawn several interesting conclusions on the relation of the chemical constitution of various organic substances including anilin dyes. Insofar as gentian-violet is concerned it is apparent that the crystal violet portion is more effective than the methyl violet and the degree of methylation would appear therefore, of importance in relation to the bactericidal effects which opens up the possibility of preparing a crystal violet with more than the six methyl groups of this dye.

Mechanism of the Bacteriostatic and Bactericidal Activity of the Anilin Dyes.—Just as we are lacking in sufficient information on the relation of chemical constitution of the anilin dyes to bacteriostatic and bactericidal activities to enable one to establish the highly desirable "laws" for aiding advances in our knowledge of the chemotherapy of these substances by synthesizing new compounds in a more orderly fashion, so are we likewise lacking in accurate information on the mechanism of their bactericidal activities. We ordinarily state that phenol, mercuric chlorid and other disinfectants kill bacteria by coagulating the proteins of their protoplasm but the process is probably not so simple and certainly is not in relation to the anilin dyes.

Genesistasis in Relation to Bacteriostasis.—As stated by Churchman[39] there is a good deal of reason for supposing that bacteriostasis may act by paralyzing the reproductive mechanism of bacteria without otherwise injurying the organisms; this is designated as "genesistasis" or the "genesistatic activity" of disinfectants. That powerful action on cell processes can be exerted by substances which do not penetrate beyond the surface of the cell has been shown by Warburg.[40] Churchman states there is evidence for the conclusion that gentian-violet has an inhibiting effect on the fission of paramecium even in dilutions which do not penetrate the cell or otherwise injure the organism; and in one instance he was able to observe a paramecium, lying in gentian-violet, begin its division but never conclude it—a striking example of genesistasis. Churchman believes that this phenomenon may be due to changes effected by the dye at the surface of the organisms and bear an important relation to the mechanism of genesistasis or bacteriostasis.

Penetration and Staining in Relation to Bacteriostasis.—As stated by Churchman, the simplest explanation for the behavior of gentian-violet and acid fuchsin toward bacteria is that the whole process is simply one of selective penetration. Penetration does not, however, "entirely account for the behavior of these dyes unless we interpret penetration to mean, not merely arrival of the dye within the bacterial membrane, but its arrival at some

particular portion of the bacterial body concerned with reproduction—a procedure which could not be made out with the microscope and which it is difficult to separate in thought from chemical affinity. It must, however, be remembered that when we speak of penetration by a dye we usually think of penetration by the colored portion of the dye since this is the only portion we can see. It might well be that the effective portion of the acid fuchsin molecule (let us say the SO_3 radical) penetrates Gram-negatives readily and kills them even though they are not stained, that is penetrated by the visible portion of the dye."

That static effects may be produced without penetration is, therefore, clear. But it is equally true that penetration of a dye may occur without bacteriostasis as shown in a splendid study by Simon and Wood[41] on the mechanism of the inhibitory action of certain anilin dyes upon bacterial development.

Ionization, Electrical Adsorption, etc., in Relation to Bacteriostasis.—According to Stearn and Stearn,[42] the staining reactions of all bacteria show that they behave as ampholytes tending to retain basic dyes in alkaline solution and acid dyes in acid solution. It might well be expected that the formation of a loose compound between any constituents of the media which are not easily decomposed by hydrolytic action, and thus "digested" by the bacteria, should interfere with the life cycles of such organisms. Bacteriostats, they believe, act in this way and that the behavior of bacteria toward dyes, so far as staining reaction is concerned, is well accounted for by their modification of Loeb's[43] theory of proteins applied to bacteria. On the acid side of the isoelectric point it might be expected that acid dyes could be just as effective as are basic dyes on the alkaline side. For a simple protein they might be, but they have pointed out that staining characteristics of bacteria indicate an isoelectric range between the isoelectric points of bacterial protein and bacterial lipoid, through which the protein would act as a base and the lipoid as an acid.

Basic dyes find their task very simple, for a solution on the alkaline side of the isoelectric point of bacterial protein is also on the same side of the isoelectric point of the much more strongly acidic lipoid, and there is thus no interference with action. Throughout the isoelectric range, however, the lipoid is working against an acid dye and even though the reaction is favorable for dye-protein combination it is also favorable for lipoid-protein combination into a conjugate protein, and we have both lipoid and acid competing for the protein and a very much greater quantity of acid dye would have to be used for the same inhibitive effect than of basic dye under the former set of conditions.

For acid dyes to have an effect commensurate with the well known effectiveness of basic dyes when used properly, it would be necessary to lower the pH to a value below the isoelectric point not only of the protein but also of the lipoid. In general this will throw the reaction over to an acidity so great that inhibition of growth will take place without the addition of dye at all, so that the practical application of high dilutions of acid dyes seems limited.

Churchman states that the method of ionization of the two groups of dyes whose action has been studied by him may explain their behavior. It is suggestive in his opinion that one group is basic and the other acid and that if this kind of explanation is the correct one it must be that Gram-positive spore bearers and Gram-negatives differ in their H ion concentration. He also mentions that since the basic dyes are electro-positive while the acid dyes are electro-negative that it is tempting to explain selective activity

on the basis of electrical absorption, an interesting thought deserving of further investigation.

Of additional interest in this connection is the work of Burke and Graves[44] on the influence of alkali in dye therapy indicating that bacteriostatic and bactericidal action of many of the dyes varies with the hydrogen ion concentration of the medium surrounding the organisms. With an increase in alkalinity there is, in their opinion, with but few exceptions, an increase in the action of dyes among which are crystal-violet, methyl-violet, gentian-violet, brilliant green, basic fuchsin, the flavins and malachite green. They believe that it is advisable, therefore, to attempt rendering the body fluids more alkaline by the administration of sodium bicarbonate or the application of an alkaline wash before a dye is applied in the treatment of localized infections.

Dye Fastness of Bacteria in Relation to Chemotherapy.—Of considerable interest in relation to the employment of dyes in the chemotherapy of bacterial infections is the question of whether or not some species may acquire or naturally possess a resistance or fastness to the anilin dyes. Simon and Wood believe that some members belonging to dye-susceptible groups of organisms exist in nature which are not inhibited by the dyes in question and that dye susceptibility may be overcome to a greater or less extent by adaptation or the acquisition of fastness (resistance).

Shiga[45] succeeded in rendering cholera bacilli resistant or fast to some dyes and Churchman has worked with strains possessing an impeccable fastness to gentian-violet, but Browning and Gulbranson[46] have stated that they were unable to produce fastness or resistance with acriflavin and brilliant green and Gay and Morrison[47] state that although their experiments are not extensive on this point, they are unequivocal and show clearly that repeated subcultures of the streptococcus in the highest non-bactericidal dilution of several of the most active dyes not only did not render the microörganisms more resistant to more concentrated solutions of the dye, but actually seemed to develop a greater susceptibility to the dye in dilutions in which it originally grew.

Various spirochetes and trypanosomes, however, have been rendered resistant to anilin dyes, arsenicals and other substances and my own experience indicates that different strains of staphylococci, streptococci, colon and typhoid bacilli may exhibit slightly varying natural resistance to the anilin dyes; I have not tried to render any one strain particularly resistant or fast to a particular dye, but am prepared to believe that this is possible by prolonged and careful experiments in which the organisms are exposed to progressively increasing but subbactericidal strengths of the dye.

Influence of the Anilin Dyes upon Phagocytosis and Antibodies.—Numerous questions naturally arise when the dyes are employed for the treatment of local or general bacterial infections in relation to their influence upon phagocytosis, antibodies and immunological reactions. For example, may these substances applied locally to infected wounds or serous membranes inhibit phagocytosis of the organisms by leukocytes? May they destroy complement and bacteriolysins by local application or intravenous injection? May they increase antibody production upon intravenous injection or absorption from the subcutaneous tissues, muscles or gastro-intestinal tract? These questions are not without interest and some practical importance in relation to the use of the dyes for therapeutic purposes.

Naturally most interest has been commanded by the influence of dyes on phagocytosis since they have been generally employed in the treatment of local infections of wounds and serous cavities. Browning and Gulbranson[48]

found that concentrations of 1:7000 malachite green and crystal-violet, 1:2000 brilliant green and 1:500 acriflavin, inhibit phagocytosis, the last mentioned being the least anti-phagocytic of the group tested and from this standpoint most desirable for the treatment of wounds by topical application. Fleming[49] and Morgan[50] have also stated that acriflavin destroys leukocytes but Davis[51] affirms that phagocytosis is still active in concentrations of the dye which are two hundred times as concentrated as the bactericidal dilution. Gay and Morrison report that final concentrations of acriflavin 1:2400 or stronger appeared to slightly depress the phagocytic activity of leukocytes for streptococci in the test tube while weaker solutions probably increased phagocytosis slightly or at least did not depress the activity of the cells. Meleney and Zau[52] however, found that intravenous injections of large doses of acriflavin to rabbits caused a leukocytosis in direct proportion to the dose; that the dye had little or no effect on the number or fragility of erythrocytes and coagulation or bleeding time and that it exerted a temporary deleterious effect on the functional activity of the polymorphonuclear leukocytes.

With the assistance of Miss Richter, I have studied the influence of solutions of various dyes upon the complement of the guinea-pig and we found the results applicable for estimating the probable effect of the dyes upon the complement to be found in exudates and in the plasma of the blood. Final concentrations of 1:100 to 1:1600 of acriflavin, gentian-violet, methylene blue and the fuchsins were in general destructive, but since the dyes are usually employed for local application in 1:1000 solutions and since further dilution occurs after contact with secretions, it would appear that appreciable or harmful degrees of complement destruction do not ordinarily occur and the intravenous injection of amounts varying from 0.005 to 0.010 gm. per kilogram of weight had no effect at all upon the complement of the plasma. Additional experiments have shown that the amboceptors, to which the bacteriolysins belong, are likewise susceptible. For example, the dyes mentioned in final concentrations varying from 1:200 to 1:600 sometimes proved destructive for hemolysin and while the results of additional experiments employing a bacteriolysin (cholera immune serum) were not as sharp or definite, yet they were essentially similar. These experiments indicate that it is not advisable to use the dyes in too high concentration for the local treatment of infected wounds, serous cavities, etc. The natural tendency is to employ them in the strongest solutions free of manifest irritation for the tissues but this practice may tend to defeat their curative activities by preventing the antibacterial properties of phagocytosis and bacteriolysis, the influence of which should not be under estimated.

May the intravenous injection of the dyes increase antibody production? A large amount of work has been done with trypan-red and other dyes in relation to antibody-production in trypanosomiasis, but the subject has not commanded interest in relation to bacterial infections although at the present time both acriflavin and gentian-violet are being injected intravenously in the treatment of bacteremias by streptococci, staphylococci and other organisms.

In my experiments I have not found acriflavin, gentian-violet or acid fuchsin, in dose of 0.010 gm. per kilogram by intravenous injection every five days for 4 to 6 doses, to appreciably influence either the complement of the blood of rabbits, natural antibody (anti-sheep hemolysin) or immune antibodies (typhoid bacteriolysin and agglutinin). When due allowance was made for natural variations among animals and unavoidable experimental error, the control animals showed approximately the same amounts

of complement and antibody in the blood as the animals treated with the dyes. It was observed that gentian-violet, acriflavin and acid fuchsin at least were without effect in stimulating the hemolysin producing tissues of the rabbit to greater activity and similar results were observed in a set of animals immunized by intravenous injections of cholera vaccine. It may be that a part of the bactericidal effect of gentian-violet and acriflavin injected intravenously in the treatment of bacteremias by streptococci and staphylococci, is due to increased leukocytosis as well as the mobilization of various enzymes, but I doubt that the dyes actually increase antibody or complement production by stimulation of the bone marrow and other tissues believed to be concerned in their production.

Toxicity and Pharmacological Action of the Anilin Dyes in Relation to Chemotherapy.—Since some of the anilin dyes and especially gentian-violet, rivanol, acriflavin and proflavin are sometimes injected intravenously in the treatment of streptococcus, staphylococcus and other bacteremias of human beings, it is important to enquire into the matter of their toxicity and pharmacological action. As would be expected in view of the complicated chemistry and preparation of these substances, toxicity varies considerably with the different dyes and indeed, with different lots of the same dye prepared in different laboratories. It is imperative in the interests of safety to select for intravenous injection only those dyes especially prepared for intravenous injection by processes of purification to remove the numerous impurities which may be present and dyes suitable for ordinary bacteriological work may be quite too toxic and unsuitable for intravenous injection.

Toxicity of Gentian-violet, Acriflavin, Rivanol and Other Anilin Dyes for the Lower Animals by Intravenous Injection.—Churchman and Herz[53] state that rabbits sometimes stand doses of *gentian-violet* as large as 10 c.c. of 1:200 solution by intravenous injection without apparent immediate or subsequent ill effects; this dose may be as large as 0.025 gm. per kilogram of weight, corresponding to over 1.5 gms. for an adult human being of about 140 pounds. In other experiments, however, these injections have produced violent convulsions and death with pulmonary edema or no discernible changes other than staining of the tissues. The authors do not state whether these effects were produced by the same lot of dye or by gentian-violet prepared by two different laboratories. If produced by the same dye it is indeed difficult to explain the phenomenon unless some animals possess an unusual natural susceptibility to the dye. However, if produced by gentian-violets of different manufacture it is not difficult to explain the results, since I have found one gentian-violet withstood by rats without apparent ill effects in dose higher than 0.1 gm. per kilogram, whereas the dye prepared by a second laboratory produced acute convulsions and death in dose of about 0.025 gm. per kilo, approximately the amount injected by Churchman and Herz.

Young and Hill[54] report that the intravenous injection of normal rabbits with gentian-violet killed in dose of 0.020 gm. per kilogram in five hours. However, single doses of 0.005 to 0.010 gm. per kilogram have been well tolerated in every instance. Repeated injections, given three times a week, have shown that of three rabbits given 0.005 gm. per kilogram, two died after the seventh injection, one tolerating seven injections well. Two rabbits died after four doses of 0.0075 gm. per kilogram. Of four rabbits given 0.010 gm. per kilogram, one died after the fifth dose, one after the fourth, and two after the second, an average of about three doses.

Spencer[55] reports that the maximal tolerated dose of neutral *acriflavin* for the mouse was about 0.4 c.c. of 1:5000 per 20 grams of weight; this corresponds to 0.004 gm. per kilogram which is much more toxic than I have

found neutral acriflavin to be for rats by intravenous injection. Meleney and Zau state that with lethal doses of neutral acriflavin administered to rabbits by intravenous injection, death is due to profound degenerative changes in the convoluted tubules of the kidney and to central degeneration in the liver.

Morgenroth and his associates state that the maximum tolerated dose of rivanol for mice is 0.3 c.c. of a 1:200 solution per 20 gm. of body weight by subcutaneous injection and corresponding to 0.075 gm. per kilo. By intraperitoneal injection the dose is 0.5 c.c. of 1:600 solution and by intravenous injection 0.5 c.c. of a solution 1:1500, corresponding respectively to 0.04 and 0.016 gm. per kilogram. The immediate lethal dose for a rabbit is 0.050 gm. per kilo intravenously and 0.1 gm. subcutaneously. Resorption from the tissues takes place slowly. Death occurs from cessation of breathing. The rapid intravenous injection of 0.010 gm. produces temporarily a marked depression of the blood pressure in a rabbit. The effect of the same dose administered slowly is less intense. In the subcutaneous tissues of mice and horses solutions of 1:500 to 1:1000 are tolerated without any injurious effect on the tissues. More concentrated solutions cause infiltrations.

My own toxicity tests, conducted with the assistance of Miss Anna Rule, and employing white rats of 100 to 200 grams weight, have yielded the following results expressed in terms of the *maximum tolerated doses* over a period of at least two weeks. The solutions varied from 0.5 to 1 per cent. and were injected at a constant rate of about 2 c.c. per minute as described in Chapter II.

Gentian-violet (C and B)	0.125 gm. per kilogram
Gentian-violet (N)	0.025 gm. per kilogram
Acriflavin (N)	0.035 gm. per kilogram
Acid fuchsin (C and B)	0.130 gm. per kilogram
Basic fuchsin (C and B)	0.025 gm. per kilogram
Methylene-blue (C and B)	0.050 gm. per kilogram
Rivanol	0.050 gm. per kilogram

It is interesting to note that acid fuchsin prepared in saline solution is generally less toxic than basic fuchsin prepared in distilled water. All of the dyes produce staining of the tissues and it is stated that some, especially fluorescein, are more toxic when animals are exposed to sunlight. Proflavin is stated to be about half as toxic as acriflavin.

Toxicity of the Dyes for the Lower Animals by Intrapleural and Intracisternal Injection.—Since gentian-violet and acriflavin have been injected into the pleural cavities in the treatment of pleuritis, I have determined the toxicity of these in addition to acid and basic fuchsin and methylene-blue by this route of administration. Normal rats and rabbits were employed and the general results have been that all of these dyes were approximately 0.5 per cent. more toxic by this route than by intravenous injection.

I have also employed some of the dyes in the chemotherapy of experimentally produced streptococcus and staphylococcus meningitis of rabbits; toxicity tests employing normal rabbits injected intracisternally showed that the maximum tolerated dose of gentian-violet was from 0.001 to 0.002 gm. per kilogram, being at least ten to twenty times more toxic by this route than by intravenous injection. The maximum tolerated dose of acriflavin was between 0.002 to 0.003 gm. per kilogram and methylene-blue and acid fuchsin were tolerated in about the same or slightly larger doses. The total amount of fluid injected was about 0.25 c.c. per kilogram, as this amount of saline solution does not produce untoward effects by pressure and is a

convenient amount to inject by this route. Subdural injections in the lumbar region of rabbits and through trephine openings of the skull over the frontal lobes of the cerebrum yielded approximately the same results.

Mechanism of the Toxicity, Fate, Elimination and Pharmacological Action of the Anilin Dyes in the Lower Animals.—Comparatively little is known of the pharmacological action of the anilin dyes, largely because their use in the treatment of disease has been very limited until the last few years. Methylene-blue administered by subcutaneous or intravenous injection may cause a slight increase of blood-pressure by cardiac stimulation and is rapidly reduced to colorless leuko-compounds. It is excreted in the urine, feces, sweat and sputum, partly unchanged and partly as "methylene-azure," and has been injected subcutaneously in dose of 0.02 to 0.05 gm. as a test for renal function, the dye being normally excreted in fifteen to twenty-five minutes. All of the dyes appear to be excreted largely in the bile and urine, but the rapidity of elimination varies considerably. Beckwith[56] who has studied *in vitro* the effects of bile, serum, erythrocytes and emulsions of the brain, muscle, lung, marrow, liver, spleen, and kidney upon the absorption and decolorization of 22 different dyes in relation to their fate *in vivo* noted that little change was wrought in any of the dyes tested. On the other hand, he believes that certain secreting and filtering tissues, such as liver, kidney, bone marrow and spleen, show a high degree of activity, lung and muscle occupying an intermediate position. Certain dyes such as acriflavin and proflavin showed no change throughout. Other stains varied in outcome according to the particular cell structure with which they were placed in contact. Some dyes were reduced to the leuko-base as methylene-blue many times and as trypan-blue once. Others were changed into products further removed from the original molecular structure. It was noted that while one dye may be eliminated in part through the bile, another may be found only in the urine. This of itself denotes a selective affinity in the first coloring matter for special cell structures which does not exist in the second dye.

Acriflavin in toxic doses by intravenous injection is said to kill by paralysis of respiration and I believe that a combination of cardiac and respiratory paralysis accounts for the acute deaths of rabbits and other of the lower animals injected intravenously, intracisternally or intrapleurally with toxic amounts of the anilin dyes.

Of considerable interest in relation to the mechanism of toxic reactions following intravenous injections of the dyes, is the question of their hemolyzing and agglutinating effects upon the erythrocytes. As discussed in Chapter XLV, these effects are regarded as important in relation to the toxic reactions following the administration of arsphenamin and other organic arsenicals, and the subject always commands attention when drugs are injected intravenously, as well as the possibility of their producing precipitates with the proteins of the plasma. With the assistance of Miss Richter, I have studied these effects with interesting results as follows:

Dye	Hemolysis (Washed Cells)	Hemolysis (Unwashed Cells)
Acriflavin	1:200 (slight)	not in 1:100
Gentian-violet	1:12,000	1:800
Acid fuchsin	1:400 (slight)	not in 1:100
Basic fuchsin	1:200 (slight)	not in 1:100
Methylene blue	1:100 (slight)	not in 1:100

The results of the *hemagglutination* and *serum precipitation* tests were as follows:

Dye	Agglutination (Washed Cells)	Agglutination (Unwashed Cells)	Precipitation
Acriflavin	1:3200	1:400	not in 1:500
Gentian-violet	not in 1:100	not in 1:100	not in 1:500
Acid fuchsin	1:800	not in 1:100	not in 1:500
Basic fuchsin	1:800	not in 1:100	not in 1:500
Methylene blue	1:800	1:100	not in 1:500

Bohland[57] states that acriflavin agglutinates erythrocytes and Spencer[58] found it hemolytic in dilutions as high as 1:4000 to 1:8000 but free of agglutinating activity for unwashed human corpuscles in dilutions of 1:2000 and higher. Spencer also observed that slight hemolysis occurred *in vivo* within an hour after the intravenous injection of rabbits with 0.1 gm. per kilogram of weight.

From the standpoint of a possible relationship between intravascular hemolysis and hemagglutination and acute toxic reactions, most interest is commanded by the results observed with unwashed corpuscles since it is apparent that serum and doubtless the plasma, afford a great deal of protection against both reactions. Acriflavin has proved most agglutinative and gentian-violet most hemolytic, but both effects are relatively slight in the presence of serum and I doubt if these reactions are produced *in vivo* by the amounts ordinarily given or exert any important rôle in the production of toxic reactions similar, for example, to hemolysis and hemagglutination in relation to the acute toxic reaction following the intravenous injection of acid solutions of arsphenamin. At least, additional experiments conducted by injecting the dyes intravenously into rabbits in dose of 0.020 gm. per kilogram and examining the blood of the right auricle and lungs did not reveal any evidences of hemagglutination or hemolysis *in vivo* and all tests for precipitation of proteins yielded negative results.

The acute toxic reactions of the anilin dyes appear, therefore, to be largely due to an effect upon the higher nerve centers and especially the cardiac and respiratory centers; the chronic effects due to repeated injections are probably due to injuries of the liver and kidneys as suggested by the results of a preliminary study I have recently made of the histo-pathological changes in rabbits treated with six to twelve intravenous injections of gentian-violet, acriflavin and basic fuchsin in dose of 0.005 gm. per kilogram every five days.

Toxicity of the Dyes for Human Beings.—With this review of the toxicity of some of the anilin dyes for the lower animals, their toxicity for human beings may now be discussed. Most interest is commanded by gentian-violet, acriflavin, proflavin, methylene-blue, trypan-red and rivanol, since these have been generally employed in attempts to successfully combat bacterial infections.

The dose of *gentian-violet* commonly administered by intravenous injection is 0.005 gm. per kilogram corresponding to 0.3 to 0.4 gm. for an adult of average weight (30 to 40 c.c. of a 1 per-cent. solution). As a general rule, 20 to 30 c.c. of a 1-per cent. solution has been given and this dose is fairly safe, being at least 5 to 10 times less than the maximum tolerated dose for the lower animals. Following the injection the skin and mucous mem-

branes become a dusky blue in color, suggesting severe cyanosis, but due to the dye, and usually disappearing within a few hours. The breathing and pulse rate may be increased with a slight increase of blood-pressure; occasionally the patient experiences a tingling sensation of the skin with abdominal uneasiness, but I have never observed any other untoward effects. It may be that some individuals are more susceptible than others but I have not encountered any so far among more than sixteen adults to whom I have given one to three injections of Coleman and Bell's gentian-violet in dose of approximately 0.005 gm. per kilogram in 1 per cent. solution *slowly* injected.

Neutral *acriflavin* and *proflavin* are generally administered in dose of 0.005 to 0.010 gm. per kilogram corresponding to 0.3 to 0.7 gm. for an adult of average weight; usually the dose is 30 to 50 c.c. of a 1-per cent. solution (0.3 to 0.5 gm.) by *slow* intravenous injection. The skin may become flushed and especially the face; both cardiac and respiratory rates may be increased for a few minutes but in the majority of cases there are no other effects. These doses are at least 4 to 5 times less than the maximum tolerated doses for the lower animals and thereby within the range of safety but it is my practice never to inject more than 20 c.c. of a 1-per cent. solution (0.2 gm.) for the first dose when the patient is profoundly toxic, since resistance is materially reduced by severe bacterial infections.

Methylene-blue has been generally administered by injestion in dose of 0.15 gm. (2½ grains) without untoward effects.

Trypan-red has been injected intravenously in dose of 1 gm. in a 0.2 per cent. solution without ill effects; I have had no experience with it in the treatment of human subjects.

Rivanol is usually employed by local application to wounds but according to Morgenroth, may be administered intravenously with safety in dose of 30 to 50 c.c. of 1:1000 solution for adults, corresponding approximately to 0.0005 to 0.0008 gm. per kilogram or about 20 to 30 times less than the maximal tolerated dose.

By local application in solutions of 1:500 to 1:1000 strength the dyes are well borne by wounds and such serous membranes as the pleural, subarachanoid and joint cavities. I have repeatedly injected solutions of these strengths into these parts of normal rabbits without finding signs of irritation in the way of exudates or such histological evidences as hyperemia, serous and cellular exudations. Stronger solutions however, while borne insofar as duration of life is concerned, may produce varying degrees of hyperemia and cellular exudations and especially of the meninges following subdural injections.

Mechanism of Curative Activity of the Anilin Dyes in Bacterial Diseases. Before taking up the question of the actual curative properties of the anilin dyes in bacterial infections of man and the lower animals it may be well to briefly summarize our present knowledge of the mechanism of their antibacterial properties when applied locally to infected membranes or injected intravenously.

Doubtless their curative effects are mainly due to direct penetration of organisms followed by such changes in the life processes as results in an interference with proliferation (bacteriostasis) or death (bactericidal). Just how these effects are produced, however, is not known; possibly there is an interference with vital activities by processes of oxidation and reduction or by the production of new compounds interfering with metabolism. In the treatment of pleuritis and other infections of closed serous cavities it is usually possible to introduce sufficient dye to raise the concentration in the

pus to bactericidal or bacteriostatic proportions but these curative effects may be neutralized by rapid fixation of the dye by tissue cells and before appreciable numbers of organisms are reached and destroyed. For this reason the parts must first be cleansed of pus before application of the dye in order to spare as much as possible for the destruction of bacteria. Likewise the intravenous injection of 0.010 gm. per kilogram may hardly raise the concentration in the blood to bactericidal proportions and especially since the dyes tend to be reduced or otherwise rapidly removed from the blood stream. But acting as adjuvants to serum therapy or administered by daily injection, some curative effects may result.

Furthermore, when the dyes are injected intravenously certain non-specific effects may aid in the curative activity. For example, the injection of rabbits with gentian-violet in dose of 0.010 gm. per kilogram usually results in a leukocytosis of moderate degree within an hour, mainly due to a total increase of the polymorphonuclear neutrophilic leukocytes, lasting for at least two hours and reaching normal proportions in twenty-four hours. Spencer reports that the intravenous injection of rabbits with acriflavin in dose of 0.1 gm. per kilogram results within three hours in a leukocytosis of over 100 per cent. which was only somewhat reduced by the end of twenty-four hours.

The serum proteases, however, are not constantly or markedly increased. My student, Dr. Ling, found the following values in normal rabbits injected intravenously with gentian-violet in dose of 0.010 gm. per kilogram, the results being expressed in terms of the number of milligrams of non-coagulable nitrogen per 100 c.c. of serum after 48 hours digestion:

	Rabbit No. 1	Rabbit No. 2	Average
Before injection	1.4	0.7	1.05
4 hours after injection	1.4	1.4	1.4
24 hours after injection	0.7	0.7	1.05

The slight increase noted four hours after injection may represent an actual result of the dye but the results are practically within the range of normal variations for rabbits.

Anilin Dyes in the Chemotherapy of Experimentally Produced Local and General Bacterial Infections.—But comparatively little work has been done with the anilin dyes in the treatment of experimental bacterial infections of the lower animals except in tuberculosis, although they have been quite widely employed in the treatment of local and systemic infections of human beings. It is true that experimentally produced infections are usually severe and place a heavy strain upon the curative activities of a medicament, but yet the logical procedure is to first apply studies of this kind, whenever possible and before clinical application is made in order to avoid the pitfalls of hasty and erroneous conclusions regarding the practical curative activity of any agent under study.

Anilin Dyes in the Chemotherapy of Experimental Staphylococcus, Streptococcus and Pneumococcus Infections.—A notable example of orderly investigation is afforded by the work of Morgenroth and his associates[59] with acridin derivatives and especially rivanol, in experimental staphyloccoccus and streptococcus infections. As described in Chapter IV, they have worked out a method for producing deep streptococcus and staphylococcus abscesses in mice by the subcutaneous injection of small amounts of culture and have used these experimentally produced infections for studying the curative

effects of new drugs *in vivo*. They report that tests with as many as forty different strains of streptococci have shown that the injection of mice with 1 c.c. of 1:40,000 solution of the drug (approximately 0.00125 gm. per kilogram) is sufficient for destroying these organisms within twenty-four hours; in staphylococcus infections the required dose is about twice as large or 1 c.c. of 1:20,000 solution (0.0025 gm. per kilogram). Hussey[60] states that silver and gold salts with the acridins have proved curative in experimental streptococcus and anthrax infections and that the silver compounds are of clinical value in the treatment of streptococcus bacteremia, gonococcus infections and polyarthritis.

Gay and Morrison[61] have reported upon some of the dyes and especially acriflavin, in the treatment of experimentally produced streptococcus pleuritis and empyema of rabbits but do not believe that the outlook for developing a dye therapy for infections of closed cavities is very promising; it is to be remembered, however, in this connection, that no attempt was made in their experiments to first drain and cleanse the pleural cavities before the introduction of the dye, as advised and emphasized by Churchman[62] in his work upon the dye therapy of infected joints and pleurae with gentian-violet. Meleney and Zau[63] state that neutral acriflavin injected intravenously failed to favorably influence streptococcus infections of rabbits and Hirschfelder and Winternitz[64] failed to influence the course of experimental pneumococcus pneumonias of rabbits treated with trypan-blue, trypan-red, basic fuchsin, acid fuchsin, crystal-violet, malachite green, gentian-violet, erythrosin and other substances like salvarsan, sodium antimony thioglycollate, sodium iodo-o-oxy-quinolin sulphonate, potassium guaracolsulphonate (thiocol), hexamethylenamin, etc.

With the assistance of Dr. Malcolm J. Harkins, I have investigated the curative properties of acriflavin and gentian-violet in mice, rats and rabbits infected with virulent streptococci, staphylococci and pneumococci. Mice were inoculated subcutaneously according to Morgenroth's method and the dyes injected subcutaneously or intraperitoneally, the first dose being given four hours after infection and subsequent doses at daily intervals. Controls were of course included on the cultures alone and the two dyes. Gentian-violet was given in dose of 0.005 to 0.010 gm. per kilogram and neutral acriflavin in dose of 0.010 gm. per kilogram. The untreated controls generally succumbed in forty-eight to seventy-two hours with well-developed local lesions in the streptococcus and staphylococcus infections. The streptococci and anthrax bacilli were also usually to be found in the blood of the heart. The results observed among the treated animals were largely negative; in some instances, not more than 10 per cent. of the animals, some appreciable effects were observed in the prolongation of life for one or two days beyond the survival of the controls and the effects of both dyes were approximately similar.

Since white rats possess a higher natural immunity to streptococci, they were infected by the intravenous injection of 0.5 c.c. of a twenty-four-hour broth culture of a highly virulent hemolytic strain of streptococcus. The two dyes were injected intravenously or intraperitoneally in dose of 0.005 to 0.010 gm. per kilogram, the first dose being given four hours after infection. The results, however, were negative since the treated animals succumbed with a streptococcus bacteremia in about the same time as the untreated controls (twenty-four to forty-two hours).

Rabbits were infected by daily intravenous injections of 0.5 c.c. of 1:1,000,000 dilution of twenty-four-hour broth cultures of this highly virulent streptococcus in an attempt to produce a milder and more prolonged bactere-

mia. Both dyes were injected intravenously in dose of 0.005 to 0.010 gm. per kilogram, each dose being given four hours after inoculation. The controls generally survived for four to five days, succumbing with bacteremia and yielding positive blood cultures during life and heart cultures after death. Neither dye appreciably influenced the duration of life and when due allowance was made for individual variations probably due to natural resistance, our results were interpreted as negative.

With the assistance of Miss Anna Rule, I have also produced acute suppurative meningitis in rats, guinea-pigs, dogs and rabbits by the subdural or intracisternal injection of virulent streptococci, pneumococci and staphylococci. Gentian-violet and neutral acriflavin were administered by intracisternal injection in dose of 0.0001 to 0.002 gm. per kilogram, the first dose being given four hours after infection and subsequent doses at daily intervals. As a general rule, however, the results were negative in that the treated animals succumbed in about the same time as the untreated controls, showing cloudy spinal fluids containing enormous numbers of cocci and in the streptococcus infections, with the organisms in the heart blood. Animals receiving as many as six to ten injections of the drugs alone, however, survived without appreciable harmful effects, indicating that both dyes in the doses given were well tolerated by this route of administration.

We have also worked with rivanol but were unable to demonstrate any constant or well defined curative activities in these experimental infections and I believe the same applies to other anilin dyes of the triphenylmethane series. Mention may also be made that Spencer found acriflavin unable to check or control pneumococcus infections of mice. Churchman[65] has never been able to kill organisms circulating in the blood by intravenous injections of gentian violet and while there is some evidence in the literature that it may at some time prove possible to produce a *sterilisans magna* in this way, certainly at the present time there is nothing to suggest that it is now possible to do for bacteria what quinin does for malaria.

Anilin Dyes in the Chemotherapy of Experimental Infections Produced by Typhoid Bacilli and Other Gram-negative Bacilli.—Since acid and basic fuchsin have been shown by Churchman to possess a reverse selective activity for Gram-negative organisms and especially *B. coli*, it would appear that these dyes as well as acriflavin and others found to possess a high bactericidal activity for typhoid bacilli *in vitro*, may be worthy of study in relation to the chemotherapy of infections produced by typhoid and paratyphoid bacilli, colon, cholera, dysentery and other bacilli of this large Gram-negative group. Churchman has found that the local application of solutions of fuchsin to wounds infected with the Gram-negative *B. pyocyaneus* may remove these organisms, but I have not been able to locate any reports bearing upon the dye therapy of localized lesions experimentally produced by Gram-negative organisms, either bacilli or cocci except the investigation by Beckwith,[66] on the chemotherapy of experimentally produced typhoid carriers in rabbits. He succeeded in producing this state by the method developed by Gay and Claypole[67] and investigated the curative activity of a number of dyes but found them ineffective for sterilizing gall-bladders, containing *B. typhosus* in the living body. New fast green 3B offered possibilities because it retains its activity in serum and in bile and is excreted through the bile when administered intravenously, but this dye was not effective in clearing up the carrier condition of all animals. Uhlenhuth and Messerschmidt,[68] working with rabbits rendered typhoid carriers by direct gall-bladder inoculation, state that while spontaneous cures occur in about three per cent. yet the intravenous and intramuscular injection of methyl violet stains the bile

and upper intestinal tract and cures the majority of animals; negative results occurred with the gold, mercury and copper salts of fluorescein and safranin.

Dr. Harkins and I have been experimenting with typhoid and colon infections of rabbits treated with intravenous injections of acid and basic fuchsin, acriflavin and other dyes, but owing to the difficulty of producing sufficiently uniform infections and especially bacteremias, our therapeutic results are too difficult of proper evaluation to warrant any statement at the present writing. Our work is being continued however, because it may be quite possible to develop a dye therapy for local colon bacillus infections as well as for typhoid and paratyphoid fever; indeed, as will be discussed in the succeeding chapter, mercurochrome injected intravenously, has yielded encouraging results in the treatment of *B. coli* abscesses and the dyes may also prove of value in these and similar infections.

Anilin Dyes in the Chemotherapy of Experimental Infections Produced by Tubercle, Anthrax and Other Gram-positive Bacilli.—Naturally a large amount of investigation has been devoted to the subject of the chemotherapy of experimental tuberculosis, infected guinea-pigs and rabbits (cornea) being usually employed; an excellent account of these studies is given by Wells, DeWitt and Long.[69] DeWitt has kept guinea-pigs infected with tubercle bacilli, saturated for about two months with trypan-red and trypan-blue; they lived somewhat longer than the controls but ultimately died of generalized tuberculosis. Since these dyes penetrate the tubercle so well, it was thought they might be used to carry in some more effective bactericidal agents and trypan-blue was therefore combined chemically with silver, copper, iron and mercury. Only the two mercury salts showed increased bactericidal action, the guinea-pigs inoculated with tubercle bacilli which had been exposed to these developing neither local nor general tuberculosis. Treatment of tuberculous guinea-pigs with these metal compounds of trypan-blue, copper, iron and silver salts, failed to affect the progress of the disease, while the animals treated with the mercury salt lived somewhat longer and had much less tuberculous involvement. Hence DeWitt concluded that trypan-blue and trypan-red, either as the sodium salts or as any one of the metal salts used in her experiments have failed to kill the tubercle bacilli either in the test tube or in the guinea-pig. Lewis and Kraus have also produced a large number of new compounds of trypan-red or trypan-blue combined with iodin, phenol and other substances and while some appeared to influence the vigor and rate of formation of blood-vessels and connective tissue around tubercles in the eyes of rabbits and while some were developed capable of penetrating tubercles, sometimes more or less specifically, none have cured tuberculosis in guinea-pigs. Von Linden[70] has described rather encouraging therapeutic results in six guinea-pigs inoculated with tubercle bacilli and treated with daily subcutaneous injections of methylene-blue iodid in dose of 0.2 to 0.4 c.c. of a 1:1000 solution, but DeWitt[71] has made an especially extensive investigation of methylene-blue chlorid and iodid and new compounds of these dyes and observed that they sometimes modified the disease and prolonged the lives of the animals but yet in no single case was tuberculosis cured by any of them.

None of the dyes so far tested, therefore, have shown any definite therapeutic power in experimental tuberculosis in guinea-pigs beyond some prolongation of life, and some lessening of the severity of the disease, although the penetrating and bactericidal or bacteriostatic powers were good. It is still possible, however, that some of the easily diffusible dyes may be used as carriers for more efficient therapeutic substances, which may reach in this way the tuberculous tissue which they could not otherwise attain.

Petroff[72] found acriflavin and proflavin by subcutaneous injection without effect in the treatment of guinea-pigs inoculated with a highly virulent culture and Smith[73] observed that while acriflavin, proflavin, and their silver compounds, acridinum-yellow, and acridin-orange possess a high degree of inhibition on the growth of the tubercle bacillus *in vitro*, they do not alter the pathogenicity of the tubercle bacillus when exposed to their action at 38°C. for forty-eight hours. Furthermore, experiments made to determine whether the serum of animals treated with proflavin would show inhibiting or bactericidal properties for the tubercle bacillus yielded negative results and proflavin, acriflavin, and the silver compound of the latter applied in the treatment of experimental tuberculosis in guinea-pigs and rabbits had no beneficial effects on the tuberculous processes.

Comparatively little work has been reported upon in the chemotherapy of anthrax, tetanus, gas bacillus and other infections by Gram-positive bacilli. Since gentian-violet and other triphenylmethane dyes show such well marked selective bacteriostasis for Gram-positive spore bearing bacilli, it may be expected that these dyes may favorably influence infections produced by these organisms. Dr. Harkins and I have observed that gentian-violet administered intravenously and intraperitoneally to mice and rabbits infected with virulent anthrax exerts some degree of curative activity by lessening temporarily the severity of the bacteremia with prolongation of life, but so far we have not been able to cure animals in which the infection was given a twenty-four hour or longer start. The results are sufficiently encouraging, however, to warrant our advising the intravenous injection of gentian-violet in the treatment of those cases of human anthrax showing the bacilli in the blood, which always give a very grave prognosis; it may be also worth while to apply a dressing of gentian-violet to malignant pustules and especially after excision. Neufeld and his colleagues[74] state that brilliant green, crystal and methyl violet and dahlia have yielded encouraging results in experimental anthrax infections; acridin orange and aurophosphin were likewise slightly effective in experimental chicken cholera infections.

The dyes have been used in the treatment of experimental *B. tetani* infections, but with negative results; I have not been able to find, however, any records of work devoted to the chemotherapy of experimental infections by *B. welchii, B. maligni edematis* or other Gram-positive spore bearers producing wound infections. This would appear to be, however, a field worthy of investigation.

Anilin Dyes in the Chemotherapy of Bacterial Diseases of Man.—I shall reserve for Chapter VIII a more complete discussion of the practical value of the anilin dyes in the treatment of various bacterial infections of human beings, but a general statement of the applications and reported results may be proper at the present time.

Naturally the dyes have been mostly employed for the disinfection of wounds and localized infections of mucous membranes. Thus malachite green, brilliant green, gentian-violet, fuchsin, acriflavin, proflavin, rivanol, etc., have been employed for the treatment of infected wounds and apparently with some success although thorough preliminary cleansing and especially with alkaline solutions are required for the best results. It may be stated, however, that the dyes have not yielded as good results as Dakin's solution in infections of this kind.

Gentian-violet, brilliant green, acriflavin, etc., have also been employed for the disinfection of the throat and nose of diphtheria bacilli and meningococci, but with indifferent success, largely due to the difficulty of removing

the mucoid secretions sufficiently well to permit the penetration of the dyes into crypts where the organisms are especially likely to persist.

Acriflavin, proflavin and other dyes have also been employed in the treatment of infections of such mucous membranes as those of the mouth (in gingivitis), the eye, the urethra and vagina. Success is claimed by some and denied by others but many of the reports are of a favorable character.

Gentian-violet and acriflavin have also been employed for the treatment of pleuritis and infections of the larger joints and the results have been mainly good when the pus was first removed and the infected tissues cleansed before the injection of the dyes. This would appear to be quite a promising field for dye therapy and I believe there are also encouraging possibilities in the treatment of those dreaded and almost invariably fatal forms of meningitis caused by streptococci and pneumococci as well as of peritonitis caused by these and other organisms. Morgenroth and others have also reported the successful treatment of furuncles, carbuncles, buboes, suppurative mastitis, pelvic abscesses, etc., with acridin dyes and especially rivanol.

Gentian-violet, acriflavin, rivanol and other dyes have been used with apparent success in the treatment of staphylococcus and streptococcus bacteremias; indeed these would appear as special diseases calling for chemotherapeutic measures alone or as adjuvants to serum therapy and some notably successful results have been recorded.

CHAPTER VI

ETHYLHYDROCUPREIN (OPTOCHIN) AND VARIOUS CINCHONA DERIVATIVES IN THE CHEMOTHERAPY OF PNEUMOCOCCUS AND OTHER BACTERIAL DISEASES

While the anilin dyes were among the first substances to be used for selective bacteriostasis and bactericidal activity and especially *in vitro*, in relation to the isolation of organisms, yet to cinchona derivatives belongs the distinction of being first employed for systematic efforts in the development of an efficient chemical disinfection of animals with an experimentally produced generalized bacterial infection. It has been long and generally known that quinin possesses certain bacteriostatic and bactericidal properties, and there is a long-standing tradition, endorsed by such clinicians of an older day as DaCosta and Bartholow,[1] that quinin given sufficiently early and in sufficiently large dose, will arrest an attack of pneumonia. But influenced less by these reports and the successful treatment of malaria than by the effects of quinin compounds in experimental trypanosomiasis, and by

the fact that certain peculiar biologic relationships (as bile solubility) have been found by Schilling[2] and Neufeld[3] to exist between trypanosomes and spirilla on the one hand and pneumococci on the other, Morgenroth and Levy[4] chose quinin and its derivatives as a basis and lead for chemotherapeutic studies in experimental pneumococcus infections. Best results were observed with optochin (ethylhydrocuprein) a synthetic derivative of hydroquinin (methylhydrocuprein) which latter exists in the cinchona bark or can be prepared synthetically. In experimental infections of mice the new drug was found to prevent the development of infection in some 90 per cent. of animals in which treatment was given after inoculation. Later, Guttman,[5] Morgenroth and Kaufman,[6] and Levy[7] reported further experiments indicating the protective and curative action of ethylhydrocuprein (base) and its hydrochlorid in experimental pneumococcus infections in mice.

While optochin (meaning the "best cinchonin") and its soluble salt, the hydrochlorid of ethylhydrocuprein, now marketed under the name "numoquin," have been found highly destructive for pneumococci *in vitro* and of some curative activity in the treatment of mice infected with these organisms, yet both have failed to fulfill early expectations in the treatment of pneumococcus pneumonias of human beings; but yet they are not without great interest and some practical value and Morgenroth,[8] continuing his efforts, has more recently produced isooctylhydrocuprein ("vuzin") for the treatment of staphylococcus, streptococcus and gas bacillus infections. The cinchona derivatives have proved, therefore, worthy of close attention in relation to the chemotherapy of bacterial infections and in this chapter I shall largely confine my discussion to a consideration of their bacteriostatic and bactericidal activities *in vitro* and their toxicity and curative activity in experimentally produced infections.

Selective Bacteriostatic and Bactericidal Activity of Ethylhydrocuprein (Optochin) and Other Cinchona Derivatives in Vitro in Relation to Chemotherapy.—Morgenroth and Levy found that ethylhydrocuprein possessed a high degree of pneumococcidal activity *in vitro* and this observation has been amply confirmed, although, as would be expected, the pneumococcidal dilutions published by different investigators have varied greatly according to the technic employed. Wright and his associates[9] found that a dilution 1:400,000 in serum killed pneumococci and that its bactericidal activity was about half as efficient as in a menstrum of water; they used, however, a pipet method carrying but a very few organisms and the bactericidal dilutions were, therefore, rather high. But in relation to chemotherapy, the observation that ethylhydrocuprein preserves a high degree of pneumococcidal activity in serum is of considerable importance as it indicates the probability of maintaining some bactericidal activity when absorbed into the blood.

Other cinchona compounds are much less pneumococcidal *in vitro*. Russo,[10] for example, observed that ethylhydrocuprein hydrochlorid in 1:16,000 kills pneumococci in three hours at room temperature, while the bactericidal activities of the hydrochlorids of isoprophylhydrocuprein, isobutylhydrocuprein, isbamylhydrocuprein, quinin and hydroquinin were much less.

Furthermore, ethylhydrocuprein is far more bactericidal for pneumococci than for other organisms. Moore[11] observed that while this compound was pneumococcidal in dilutions from 1:20,000 to 1:10,000,000 for different serological strains of pneumococci, yet streptococci, staphylococci, *M. catarrhalis*, *B. coli*, *B. typhosus* and *B. friedländer*, were not killed in dilutions of 1:10,000 except in the case of one strain of streptococcus which was killed in 1:20,000. Quinin hydrochlorid was pneumococcidal in 1:5000 to 1:10,000 and bactericidal for these other organisms in 1:1000 to 1:5000 dilutions. The specificity of the bactericidal action of cinchona derivatives on pneumococci was also studied by Cohen, Heist and myself[12] by cross-testing their efficacy against *B. typhosus*

and *S. aureus*, while also testing the bactericidal activity of phenol, mercuric chlorid, arsenobenzol and other chemicals for pneumococci.

In a general way, the results observed with *B. typhosus* and *S. aureus* and all the quinin salts were similar; that is, the inhibiting dilution usually ranged from 1:1000 to 1:2000. The value of ethylhydrocuprein as a bactericide was from 200 to 400 times greater for the pneumococcus than for *B. typhosus* and the staphylococcus; the various quinin derivatives showed a bactericidal activity against the pneumococcus ranging from 5 to 50 times greater than against the other microorganisms.

Ethylhydrocuprein hydrochlorid and other quinin compounds act somewhat slowly on organisms including pneumococci, and demonstrate more clearly their specificity for the pneumococcus in bacteriostatic than in bactericidal tests. According to the calculated amounts of quinin contained in the various salts tested, there is no definite relation. apparent between the percentage of alkaloid present and the bacteriostatic power of the compound.

Pneumococcidal Activity of the Blood after the Administration of Ethylhydrocuprein and Quinin.—While ethylhydrocuprein and practically all cinchona derivatives preserve a high degree of pneumococcidal activity *in vitro* in a menstrum of serum, it is of special interest in relation to chemotherapy to note that the administration of these compounds to human beings and the lower animals appreciably increases the pneumococcidal activity of the blood. Wright[13] was first to observe the pneumococcidal action of the serum of human beings and mice treated with ethylhydrocuprein. He called attention to the negative results obtained with rabbits. Scott[14] and Boecker[15] likewise obtained negative results with ethylhydrocuprein in the treatment of pneumococcus infections in rabbits. Moore[16] in an extensive study of this subject observed that the serum of rabbits which have been previously treated with a single dose of ethylhydrocuprein (optochin) exerts a bactericidal action on, and, later inhibits the growth of pneumococci in the test-tube. In a later study by Moore and Chesny,[17] it was observed that when optochin hydrochlorid was given by mouth to patients suffering from acute lobar pneumonia in such amounts that they receive at least 0.024 gm. per kilogram of body weight per twenty-four hours, and when the size and spacing of the individual doses are adequately regulated, a specific pneumococcidal action appeared in their blood within a few hours, and could be maintained more or less constant for several days.

Julian Lewis[18] has also observed an increased bactericidal activity of the serum of rabbits treated with ethylhydrocuprein, but Weiss,[19] who also worked with rabbits, observed that no pneumococcidal action of rabbit serum could be demonstrated after a single large tolerated dose, after a single fatal dose, after repeated injections of tolerated doses either by oral or by intravenous routes of various cinchona derivatives including ethylhydrocuprein hydrochlorid, quinin and urea hydrochlorid, quinin dihydrobromid, and quinin chlorohydrosulphate. He quotes Scott as stating that the destructive power of the rabbit liver for quinin alkaloids is 10 times greater than that of the guinea pig or mouse. But I am not quite so sure of the correctness of these propositions in view of Moore's results and since Borow and I,[20] working with the Heist-Lacy method,[21] which we found much more sensitive and less susceptible to contamination than plating methods, observed that the administration of ethylhydrocuprein (optochin) hydrochlorid to rabbits by intravenous, subcutaneous and oral routes results in rendering the whole blood decidedly pneumococcidal. Similar but much less marked results followed the administration of other quinin compounds as the bisulphate, hydrochlorid and quinin and urea hydrochlorid. The bactericidal properties of the blood rapidly disappeared however, after the administration of these compounds had ceased.

Acquired Ethylhydrocuprein (Optochin) Fastness or Resistance of Pneumococci.—As stated by Moore and Chesney, this is a consideration of

importance in the treatment of lobar pneumonia with optochin, namely, the possibility that a dosage which is too small, apart from failing to confer a pneumococcidal action on the circulating blood, may give rise to conditions which favor the acquisition by the infecting pneumococci of a condition of resistance or fastness to the drug. Indeed Morgenroth and Kaufmann,[22] Tugendreich and Russo[23] and others have succeeded in demonstrating this possibility both *in vitro* and *in vivo* and therefore in the treatment of disease with optochin it would appear desirable to avoid such a low concentration of the drug in the blood as would permit the pneumococci to develop this property.

Mechanism of the Bacteriostatic and Bactericidal Activity of the Cinchona Derivatives.—Practically nothing has been yet discovered concerning the mechanism of the bactericidal and bactericidal action of ethylhydrocuprein and other cinchona derivatives for pneumococci and other organisms *in vitro*. Why these compounds possess a high degree of selective activity for pneumococci is likewise unknown. Something in their molecular structure probably establishes a special affinity for the protoplasm of these organisms, but how they act in producing genesistasis or bacteriostasis and bactericidal effects has not been elucidated. Very probably the mechanism is similar to that concerned in the destructive effects of quinin for the malarial protozoa and this subject is discussed with detail in Chapter XXXII. Here it may be stated, however, that while optochin (ethylhydrocuprein) is highly pneumococcidal, it is regarded as inferior in the destruction of malarial parasites indicating that it does not possess a pan-therapeutic activity, and that for the bacteria its chemical constitution renders it more especially destructive for the pneumococcus.

Chemistry of the Cinchona Compounds in Relation to the Chemotherapy of Bacterial Infections.—We may now briefly consider the very difficult and complex subject of the chemistry of ethylhydrocuprein (optochin) and other cinchona derivatives in relation to their toxicity and pneumococcidal activities. Naturally, attempts have been made to improve upon optochin, at least to reduce its organotropism or toxicity for the host, but so far with little or no success.

In the first place it may be stated that while the toxicity of salts of quinin bears some relation to their content of alkaloid (varying from 20 per cent. in the tannate to 81.8 per cent. in the hydrochlorid and 75 to 80 per cent. in ethylhydrocuprein), there is no constant relation between alkaloid content, bactericidal activity *in vitro* or protective and curative activity *in vivo*. The alkaloid itself is far inferior to ethylhydrocuprein in pneumococcicidal activity as is quinin hydrochlorid, which contains approximately as much of the alkaloid. In other words, the side chains of the molecule exerts a marked effect upon the biological properties of these compounds.

Morgenroth and Bumke[24] have stated that in their opinion the specific pneumococcicidal activity of ethylhydrocuprein is in the ethoxy-group, but that in spite of its remaining intact the bactericidal value decreases in changing ethylhydrocuprein to the corresponding ketone. Rosenthal[25] gives a good description of the chemistry of this compound, the chemical structure of optochin and other quinin compounds, including "vucin," and one of the best investigations upon the chemistry of these and new synthesized aromatic derivatives of cinchona is by Jacobs and Heidelberger.[26] Felton and Dougherty[27] have studied a number of their new compounds for bactericidal activity *in vitro*, toxicity and curative activity in infected mice and rabbits with interesting results showing a relationship between chemical constitution and biological effects.

Toxicity of Ethylhydrocuprein and Other Cinchona Derivatives in Relation to the Chemotherapy of Bacterial Diseases.—In Chapter XXX the toxicity of the ordinary salts of quinin is discussed in relation to the chemotherapy of malaria and at present I wish to briefly review the toxicity of the base optochin and its soluble salt the hydrochlorid of ethylhydrocuprein, in relation to the chemotherapy of bacterial diseases, since it is doubtless apparent that these compounds have commanded most attention in this connection although, as already stated, the ordinary salts of quinin have been employed by Cohen and other clinicians in the treatment of pneumococcus pneumonia for many years.

Toxicity for the Lower Animals.—Moore[28] found that the highest tolerated dose of ethylhydrocuprein for rabbits by subcutaneous injection was about 0.1 gm. per kilogram of weight and 0.02 to 0.05 gm. by intravenous injection. Optochin base suspended in oil was tolerated in about 0.125 gm. per kilogram by subcutaneous injection and 0.075 gm. by intramuscular administration. As stated by Moore, ethylhydrocuprein in a toxic dosage gives rise to certain characteristic symptoms in rabbits, the variety and intensity of which depend in part on the dose, in part on the route by which it is given, and in part on the location of the injection.

Smith and Fantus[29] have reported that the minimal lethal dose of ethylhydrocuprein for mice is 0.5 mg. per gram of body weight; the dose for quinin is given as slightly higher or 0.7 mg. per gram of body weight. They found that optochin will reduce blood-pressure more than quinin and cause quicker cardiac death. Hunt[30] found the lethal dose of hydroquinin to be from 0.35 to 0.33 mg. per gram, and this was confirmed by Morgenroth and Halberstadter. Webb[31] observed that the minimal fatal dose of quinin sulphate and dihydrochlorid in 1:8 dilution for monkeys by subcutaneous injection was about 0.2 to 0.25 gm. per kilogram of weight. Cohen, Heist and I[32] found the lethal and maximum tolerated doses of ethylhydrocuprein hydrochlorid and some of the salts of quinin approximately as follows per kilo of weight:

Compounds	Lethal Dose		Tolerated Dose		
	Intraven.	Intramus.	Intraven.	Intramus.	Subcut.
Ethylhydrocuprein hydrochlorid	0.06	0.5–0.6	0.02–0.04	0.03–0.07	0.08–0.1
Quinin and urea hydrochlorid...	0.05–0.06	0.5	0.02–0.07	0.03–0.08	0.09–0.15
Hydroquinin hydrochlorid.. ...	0.04–0.05	0.06 0.25	0.02–0.06	0.02–0.06	0.08–0.1
Quinin hydrochlorid.....	0.5–0.06	0.5–0.6	0.02–0.05	0.03–0.07	0.09–0.18

As a general rule, mice withstood slightly larger doses than rabbits. Individual experiments also indicated that young rabbits were more resistant than older and heavier animals, confirming the observations of Moore in this respect. With the assistance of Idsumi and Sands, I have also determined the maximum tolerated dose of ethylhydrocuprein for white rats and rabbits by intraperitoneal, intrapleural and subthecal injections[33] with these results: (a) subcutaneous injection, 0.5 to 0.55 gm. per kilo; (b) intraperitoneal injection, 1.15 gm.; (c) intrapleural injection, 0.02 to 0.04 gm.; (d) intravenous injection, 0.03 to 0.04 gm. and (e) intraspinal injection, 0.0003 to 0.0005 gm. per kilo. By intracisternal or intraventricular injection the dose is slightly less being 0.0005 to 0.0001 gm. per kilo for normal animals and about 0.0003 gm. per kilo by repeated injection for animals with acute meningitis.

Toxicity of Ethylhydrocuprein (Optochin) for Human Beings.—A few years ago ethylhydrocuprein was rather widely employed in the treatment of lobar pneumonia and toxic effects were sometimes produced. Moore[34] has studied these with particular care and stated in 1917 that only one death had been, in part, ascribed to the drug by Smith and Fantus;[35] even in this case it is not entirely clear that heart failure was occasioned by the optochin. The toxic symptoms noticed have generally been transient and have usually disappeared when the drug was discontinued. The principal ones that occur are referable to the eye and the ear. In some cases vomiting has been reported; this may be due in some instances to the bitter taste of the drug, which rivals quinin in that respect. Vomiting, however, is rather infrequent, although one disadvantage connected with it is the possibility that the drug may be ejected. In only one of Moore's cases was vomiting frequent enough to interfere with the administration of the drug and in that case it is doubtful if the optochin was the cause.

The symptoms referable to the ear comprise ringing and roaring noises and partial deafness. In six of his cases tinnitus and partial deafness were associated, and in one case there was tinnitus alone, without deafness. In every case these symptoms were transient, disappearing shortly after the drug was discontinued. Indeed, in some instances these symptoms disappeared or became less evident while the drug was still being given in full amounts.

Toxic Amblyopia in Human Beings and Rabbits.—As stated by Moore, the symptoms referable to the eyes are more serious. It is difficult to determine the percentage of recorded instances of eye trouble due to the use of the drug; a review of the literature would seem to show that about 4.57 per cent. of all reported treated patients have had transient amblyopia or amaurosis. In one recorded case has there been permanent, almost complete, blindness. In this case, reported by Oliver, the patient received 5 grains (0.3 gm.) every three hours, which would mean 2.4 gm. per twenty-four hours, a dose greater than that usually given. In all other cases of amblyopia and amaurosis reported in the literature, the visual disturbances apparently disappeared after the drug had been discontinued.

With the impairment of vision the pupils may be widened, may not react to light, and ophthalmoscopic examination may show tortuosity of the retinal vessels, and generally shows narrowing of the arteries. Whether these changes in the pupils and vessels precede the impairment of vision for any considerable time cannot be stated; they did not appear in any of Moore's cases with the exception of the one that had already developed amaurosis, although all of the patients who received the drug had daily ophthalmoscopic examinations. Optochin amblyopia is said to resemble closely that of quinin amblyopia.

There is some ground for believing that the visual disturbances may depend to a certain extent on idiosyncrasy. That a condition of susceptibility to the drug may be an important factor is indicated by the fact that some patients develop amblyopia after they have had only 2 gm. of less of optochin, whereas others do not acquire it even after they have received as much as from 10 to 16 gm. A study of the literature seems to indicate, however, that the more the daily dosage is subdivided, the less frequent are the visual disturbances. If subsequent observation bears out this point, an additional reason is supplied for not giving the drug in three large doses in twenty-four hours, which method, as shown previously, probably gives rise to considerable fluctuations in the concentration of optochin in the circulating blood. It is possible, also, that the maintenance of the body-weight relation-

ship may help to diminish the frequency of occurrence of this complication by preventing overdosage. Daily examination of the eyegrounds and the pupils may give warning of impending symptoms and thus indicate the discontinuance of the drug, or reduction of dosage.

About three years ago I had one of my students, the late Dr. Andrew L. Forster, investigate the toxic effects of quinin and urea hydrochlorid and ethylhydrocuprein hydrochlorid upon the eyes of white rabbits. Two groups of animals were employed, the drugs being administered by ingestion, subcutaneous and intravenous injection. I was surprised to learn of the really enormous total dosage required to produce toxic effects and surmise that the eyes of human beings are far more susceptible than those of rabbits, and especially to optochin (probably less so to quinin and urea hydrochlorid and other ordinary salts of quinin).

Dr. Forster summarized his study with the statement that rabbits were able to tolerate enormous doses of quinin and urea hydrochlorid and ethylhydrocuprein hydrochlorid without showing any special signs of intoxication. The first group received 238 doses, or a total of 5.55 gms. within a period of three months. This tolerance was demonstrated by the fact that all rabbits, those receiving the largest as well as those receiving the smallest doses, apparently enjoyed the same health and retained their same approximate weights.

The second group received much larger total amounts of the drugs within a comparatively short period, namely, 49 doses within four weeks or a total of 2.96 gms. The reason for this increased amount was to reach the toxic dose which appeared to be approximately 0.080 gm. per kilo given hourly for two to four doses.

It is noteworthy that during the entire period of the experiments none of the rabbits ever exhibited any corneal anesthesia, dilatation of the pupils, ischemia of the retina or constriction of the retinal arteries, evidence of visual disturbance or any other ophthalmoscopic changes in the fundus. Microscopically the first group showed perivascular infiltration of mononuclear and plasma cells in the cerebrum in three cases, and to a less degree in one case in the cerebellum. In all other cases, the pons, cerebellum and optic nerves were negative. In the retina the ganglion cell layer in all cases showed marked changes, such as vacuolization of the protoplasm and nuclei, the breaking up of the chromatin, the loss of the nuclear wall and the extrusion of its contents, the loss in staining properties, a decrease in the number of ganglion cells and the appearance of hyaline-like bodies.

Ethylhydrocuprein (Optochin) and Other Cinchona Derivatives in the Chemotherapy of Experimental Trypanosomiasis and Bacterial Diseases. With this review of the toxicity, bacteriostatic and bactericidal activities of ethylhydrocuprein (optochin) and other cinchona derivatives, we may now consider their protective and curative effects in experimental bacterial infections and especially those produced by virulent pneumococci. After all, these effects are of most interest and importance because so many factors may reduce the curative value of chemical agents displaying an extremely high selective bacteriostasis in the test-tube, as that of ethylhydrocuprein for the pneumococcus.

Ethylhydrocuprein in the Treatment of Experimental Trypanosomiasis.—I have already mentioned that Morgenroth was influenced in selecting the cinchonics as a "lead" in this work by reason of their influence upon trypanosomes and it may be of interest to first state in passing that in trypanocidal tests employing white rats infected with *T. equiperdum* and treated with intravenous injections of ethylhydrocuprein, only the maximum tolerated

dose of this drug, namely, 0.030 to 0.060 gm. per kilogram of weight, retarded the development of trypanosomiasis for 24 to 48 hours, but never succeeded in sterilizing the animals; similar results were observed with quinin bisulphate and quinin dihydrochlorid in dose of 0.060 gm. per kilogram.

Morgenroth and Tugendreich,[36] however, observed that while ethylhydrocuprein itself may fail, a combination with sodium salicylicate sometimes succeeded, while a combination of quinin with the salicylate failed. As would be expected, best results were secured by a combination of ethylhydrocuprein with salvarsan (arsphenamin) in dose of 0.0015 to 0.003 gm. per kilogram of weight.

Ethylhydrocuprein (Optochin) and Other Cinchona Derivatives in the Chemotherapy of Acute Pneumococcus Bacteremia of the Lower Animals.—When virulent pneumococci are inoculated intraperitoneally or subcutaneously in white mice, rapidly developing and fatal bacteremia develops because of the extreme susceptibility of these animals to this organism. Patches of pneumonia may be produced by injecting the organisms into the lungs directly through the chest wall, but the resulting fatal bacteremia constitutes the chief lesion.

Morgenroth and Levy originally employed mice infected with pneumococci and treated them with subcutaneous injections of optochin (base) suspended in oil. With this method 80 to 100 per cent. of mice were protected against fatal infections and the specific action of ethylhydrocuprein on the pneumococcus was found to be greater than that of any other compound of the series examined, namely, quinin, hydrocuprein and isoamylhydrocuprein. Similar results were reported by Morgenroth and Gutman [37] and confirmed by Gutman[38] working with mice and by Engiver[39] working with guinea-pigs. Levy[40] also found that mice infected with *Streptococcus mucosus*, which I believe was probably a Type III pneumococcus, could be saved against fatal bacteremia by four daily subcutaneous injections of 2-per cent. suspensions of optochin in oil in dose of 0.4 c.c. per 20 grains of weight. Moore[41] has also confirmed the curative effects of optochin base in pneumococcus infection of mice. Cohen, Heist and I,[42] however, working with the soluble ethylhydrocuprein hydrochlorid were not able to elicit as good results as reported by these investigators. As a general rule, when the drug in dose of 0.02 gm. for mice and 0.01 gm. for rabbits per kilo and the pneumococci were injected within a few seconds of each other, the life of about 20 per cent. of the animals was prolonged indefinitely, while in the balance life was prolonged but a few days beyond that of the controls. Both hydroquinin hydrochlorid and quinin and urea hydrochlorid sometimes showed slight protective value.

Further experimentation may improve the chemotherapeutic value of ethylhydrocuprein by additions, substitutions, or other molecular modifications but in my opinion optochin stands today in a position somewhat similar to that of atoxyl in the treatment of experimental trypanosomiasis. Lewis[43] and others have likewise failed to demonstrate as high curative activity of ethylhydrocuprein, in rabbits at least, but mixtures of the drug with antipneumococcus serum have yielded even better results, and it may be profitable to now review this phase of the subject.

Chemoserotherapy of Experimental Pneumococcus Infections.—Neufeld and Engwer[44] and Engwer[45] working with the pneumonias of guinea-pigs produced by the direct intrapulmonary injection of pneumococci through the chest wall according to the method of Neufeld and Ungermann, observed that the curative effects of ethylhydrocuprein were greatly enhanced by administering antipneumococcus serum at the same time. Boeknke,[46]

working with mice, stated that optochin alone protected 20 per cent. of the infected animals, serum therapy alone about 33 per cent., while a combination of the two protected as high as 90 per cent.

Observing that antipneumococcus serum for Type II pneumococci was less efficient than the serum for Type I, Moore[47] studied the influence of a combined optochin and serum treatment for Type II infections among mice and found that a single dose of optochin suspended in oil and injected subcutaneously, which by itself has practically no protective effect, was capable of increasing the threshold value of Type II serum at least 50 times, and that this effect was proportionately many times greater than a simple summation of the protective and curative effects of the two substances separately. Steinfield and I[48] also observed that ethylhydrocuprein hydrochlorid by subcutaneous injection in doses without protective value, usually increase the protective value of antipneumococcus serum Type I in a slight but definite manner in severe infections of mice and rats with homologous pneumococci. Several of the commoner compounds of quinin, as quinin and urea hydrochlorid, quinin bromid, and quininchlorohydrosulphat, given subcutaneously in doses without any appreciable influence on severe and fatal pneumococcus infections, occasionally increase the protective power of antipneumococcus serum but to a lesser extent and less regularly than ethylhydrocuprein hydrochlorid.

Ethylhydrocuprein in the Chemotherapy of Experimental Pneumococcus Meningitis.—Owing to the highly fatal character of pneumococcus meningitis and the inadequacy of methods of treatment, Idzumi and I[49] undertook a study of the effects of ethylhydrocuprein in experimental meningitis of rabbits, since systematic studies in the chemotherapy of pneumococcus meningitis do not appear to have been made. Owing to the comparative ease with which the disease may be produced experimentally, provided highly virulent cultures are available, it would appear a particularly interesting field for experimental study under conditions closely resembling a disease occurring among human beings.

Small doses like 0.001 gm. in 0.5 c.c. of salt solution per kilo of body weight usually did not produce symptoms, but sometimes produced slight congestion of the meninges at the site of the injection; 0.0005 gm., equivalent to 0.5 c.c. of a 1:1000 dilution per kilo, did not produce any symptoms or discernible changes in the meninges and was generally employed by us in the therapeutic experiments. This dose corresponds to 30 c.c. of a 1:1000 dilution per 60 kilos of weight and represents a safe dose of ethylhydrocuprein hydrochlorid for adult persons by intraspinal administration.

Therapeutic tests were now conducted with the general result that the subthecal injection of single doses of ethylhydrocuprein, in amounts of 0.5 c.c. of 1:500 and 1:1000 solution per kilo of body weight, had a distinct beneficial effect on the course of experimental meningitis in rabbits produced by a Type I pneumococcus of moderate virulence, when administered not later than 4 to 6 hours after the injection of organisms; when given 24 hours after the pneumococci this effect was not apparent. With a meningitis produced by a more virulent culture of Type II pneumococci, single doses of this drug had but slight or no effect on the duration of the lives of the experimental animals, but in experiments consisting in the repeated intraspinal injection of smaller doses of pneumococci followed in a few hours by ethylhydrocuprein, the protective and curative effects of the drug were more apparent. However, mixtures of specific antipneumococcus serum and ethylhydrocuprein did not yield results in the treatment of experimental meningitis produced by Type I pneumococci, superior to those observed

with the drug alone and the serum alone was without appreciable effect on the course of the experimental lesions. Similar results have been observed more recently on the treatment of acute pneumococcus meningitis of dogs[50] treated with ethylhydrocuprein (numoquin) by intravenous, intracisternal and intraventricular injection. In these the drug alone has been without appreciable effect unless the subarachnoid space was first washed out with saline or Ringer's solution. I have treated eleven cases of pneumococcus meningitis of otitic or nasal origin with the compound by spinal puncture and the daily or twice daily intraspinal injection of 15 to 30 c.c. of 1:1000 solution without a single recovery.

Lamar,[51] having shown that sodium oleate in 0.5 to 1 per cent. solution is destructive for pneumococci and that weaker solutions as 0.1 to 0.001 per cent. lessen the virulence of pneumococci and increase their susceptibility to the destructive action of antipneumococcus serum, boric acid overcoming the inhibitory influence of the protein constituents, we included a study of these substances alone and in combination with ethylhydrocuprein on the pneumococcus in rabbits with meningitis, to determine whether sodium oleate increases the susceptibility of virulent pneumococci to the destructive activity of ethylhdyrocuprein. Intraspinal injection of these mixtures appeared to prolong the lives of some infected animals and not of others, as compared with animals receiving ethylhydrocuprein alone. While sodium oleate undoubtedly reduces the vitality of pneumococci or at least increases their susceptibility to the destructive influences of ethylhydrocuprein when the organisms are exposed to the oleate *in vitro*, our results in the treatment of experimental pneumococcus meningitis in rabbits with mixtures of ethylhydrocuprein and sodium oleate have not yielded the encouraging results observed by Lamar in the treatment of experimental meningitis in monkeys with mixtures of specific antipneumococcus serum, boric acid and sodium oleate, and in our experiments the mixtures did not prove superior to those observed with only ethylhydrocuprein.

Ethylhydrocuprein, Sodium Oleate and Bile in the Chemotherapy of Experimental Pneumococcus Pleuritis.—Since these experiments on pneumococcus meningitis have indicated that it may be possible to inject enough ethylhydrocuprein into closed sacs to raise the pneumococcidal activity of the exudates without danger of irritation of the serous membranes or the absorption of toxic amounts, Sands and I[52] have conducted similar experiments on acute suppurative pneumococcus pleuritis induced in guinea-pigs and dogs as having a possible value in the treatment of pneumococcus pleuritis with empyema developing during croupous pneumonia. The results have indicated that in the treatment of pneumococcus meningitis and pleuritis, sufficient amounts of ethylhydrocuprein may be injected intrathecaly or intrapleurally to exert considerable pneumococcidal activities without irritating these membranes or causing toxic effects. When the drug is administered by mouth, intramuscularly, or intravenously, it may be so highly diluted in the blood that enough cannot be administered to raise the pneumococcidal activity of the blood sufficiently for pronounced curative effects without danger of toxicity, but in the subarachnoid and pleural sacs dilution is by spinal fluid or exudate alone and is much less than in the blood.

The experimental lesions in guinea-pigs were very severe, consisting of acute suppurative pleuritis which involved both pleurae and the external portions of the pericardium. The intrapleural administration of ethylhydrocuprein in a dose corresponding to about 2 c.c. of a 1:500 dilution per kilo of weight in each cavity, a total of 0.008 gm. of drug, had a marked curative influence in the majority of instances unless treatment was delayed longer

than 24 hours. Such a delay permitted the development of severe bilateral pleuritis, pericarditis, and pneumococcus bacteremia. Multiple injections of 1 c.c. of a 1:500 solution per kilo into each pleural cavity had an even more pronounced effect upon less severe infections. These results indicate the possibility of chemical disinfection of infected serous cavities with drugs showing a marked and selective bactericidal activity for the infecting bacterium in the presence of pus, as optochin or ethylhydrocuprein hydrochlorid for the pneumococcus, even though sufficient amounts of the drug cannot be administered by mouth, intramuscularly, or intravenously to influence a localized inflammatory process.

Vucin in the Chemotherapy of Experimental Stapylococcus and Streptococcus Infection.—As previously stated, "vucin" or isocytylhydrocuprein, prepared by Morgenroth,[53] has been found highly bactericidal for staphylococci and streptococci and has been successfully employed in 1:2000 solution for the treatment of gas bacillus infection of wounds. Stronger solutions, however, are necrotizing. Solutions as high as 1:12,000 in dose of 1 c.c. per 20 grams have been found curative for mice inoculated subcutaneously with virulent streptococci by Morgenroth's method and similar results have been observed in staphylococcus infections. I have had no experience with the compound and according to Heffter,[54] the Remedy Committee of the German Society for Internal Medicine have stated that its use is still in the experimental stage.

Mechanism of the Curative Activity of Ethylhydrocuprein (Optochin) and Other Cinchona Derivatives in Pneumococcus Infections.—As previously stated in discussing the mechanism of the pneumococcidal activity of the cinchona derivatives *in vitro*, we do not know just how they destroy organisms, unless it is by a mechanism similar to that concerned in the destruction of the malarial protozoa described in Chapter XXXII. *In vivo* the same mechanism is doubtless accountable, as ethylhydrocuprein (optochin) undoubtedly possesses a high degree of bactericidal activity for pneumococci in the blood and exudates even though it may fail to reach and destroy appreciable numbers of the organisms in the lesions of lobar pneumonia. The results of the experiments discussed above indicate that these compounds may enhance immunological destruction of pneumococci by reducing the resistance of the organisms to the bactericidal activity of the blood.

Does ethylhydrocuprein and other cinchonics tend to increase antibody production for the pneumococcus? As far as I am aware, no one has studied this problem sufficiently well to warrant an opinion, but I doubt that any such mechanism is involved. It may be, however, that ethylhydrocuprein favors the phagocytosis of pneumococci by lowering the resistance offered by the organisms and it would appear abundantly proven that phagocytosis plays an important rôle in the recovery from pneumonia and other pneumococcus infections.

Steinfield and I,[55] have found that *in vitro*, weak solutions of ethylhydrocuprein and other cinchona derivatives materially increase the phagocytosis of virulent pneumococci. In our experiments it was observed that pneumococci possessing some degree of virulence for rabbits and mice may undergo spontaneous phagocytosis by the exudative leukocytes of rabbits, but that ethylhydrocuprein hydrochlorid, quinin and urea hydrochlorid, and other compounds or derivatives of quinin in high dilutions accelerate the phagocytosis of pneumococci by rabbit leukocytes. Low dilutions of cinchona derivatives, however, were found to retard phagocytosis and induce degenerative changes in leukocytes.

The administration of ethylhydrocuprein hydrochlorid, quinin and urea hydrochlorid, and other quinin derivatives to rabbits by intramuscular injection was found to increase the phagocytic powers of the sera for pneumococci and it is probable that these quinin derivatives in high dilution accelerate phagocytosis by reducing the virulence and resistance of the pneumococci and also by stimulating the phagocytic activities of the leukocytes.

Furthermore, the intramuscular injection of ethylhydrocuprein hydrochlorid, quinin and urea hydrochlorid, and other cinchona derivatives in rats increases the total number of leukocytes in the peripheral blood while lesser degrees of leukocytosis follow the intravenous injection of these compounds.

These experiments indicate that probably a part of the curative effect of quinin and urea hydrochlorid, ethylhydrocuprein, and other cinchonics in pneumococcus infections is to be ascribed to their influence on phagocytosis, and I am inclined to attribute no small part of their curative effects *in vivo* to this mechanism in conjunction with a direct bactericidal action of the compounds.

Ethylhydrocuprein (Optochin) and Other Cinchona Derivatives in the Chemotherapy of Bacterial Diseases of Man.—In conclusion it may be stated that ethylhydrocuprein (optochin) and other cinchonics have been reported by many competent clinicians as possessing some practical therapeutic value in the treatment of pneumococcus bacteremia and pneumonia of human beings. It is true that early expectations have not been realized and that a *therapie magna sterilisans* has not been secured, but unquestionably it is possible by proper administration to raise the pneumococcidal activity of the blood and probably increase phagocytosis and these results are doubtless worth while, as I shall discuss with more detail in Chapter VIII.

Ethylhydrocuprein in 1-per cent. solution has also proven efficacious in the treatment of pneumococcus conjunctivitis and I believe it may possess some curative activity in the local treatment of pneumococcus sinusitis, mastoiditis, otitis media, as well as in pneumococcus meningitis, pleuritis and for the disinfection of the mouth in carriers.

CHAPTER VII

COMPOUNDS OF MERCURY, ARSENIC AND OTHER SUBSTANCES IN THE CHEMOTHERAPY OF BACTERIAL DISEASES

Probably no class of chemical agents has commanded as long, as much or as hopeful an interest in the chemotherapy of bacterial diseases as the inorganic and organic salts of mercury. The very fact of the well-established curative activity of mercurial compounds in syphilis was of itself sufficient for focussing attention upon their possible curative effects in bacterial diseases and almost simultaneously with the earliest developments in bacteriology, was the discovery of the extremely high bactericidal activity *in vitro* of mercuric chlorid and other salts of mercury for various bacteria. Naturally enough these observations led to the expression of most hopeful expectations in the treatment of disease, although Koch[1] showed quite early that mercury was without apparent effect in the treatment of experimental tuberculosis of guinea-pigs, despite the fact that the vapors and various soluble inorganic salts were found to be highly tuberculocidal in the test-tube.

But mercury has always had a peculiar fascination for many physicians in the treatment of bacterial infections by local application and even for the treatment of systemic infections by ingestion, intramuscular or intravenous injection, as in the use of calomel or mercuric chlorid in the treatment of typhoid fever by attempted disinfection of the intestines, the injection of the

succinimid in the treatment of tuberculosis, etc. Of course it has been long realized that the high organotropism or toxicity of the mercurial compounds constituted a stumbling block to their usefulness as disinfectants of the tissues, but experimental chemotherapeutists have frequently considered the possibility of reducing their toxicity by the synthesis of new compounds without too greatly reducing parasiticidal effects. It is well known, of course, that mercury may be so firmly bound in a molecule, as in full-complex compounds, that the compound is eliminated without much dissociation and consequently with greatly reduced toxic effects; but I shall later discuss this phase of the subject, wishing merely at this time to express the opinion that the hopes of mercury in chemotherapy are probably justified and that it occupies an important place as a "lead" in the chemotherapy of bacterial diseases and particularly since mercurochrome was discovered and found so encouraging by Young, White and Schwartz[2] in the treatment of local and systemic bacterial infections. A great deal of time and effort have already been expended in chemotherapeutic studies with the mercurials and especially in relation to the treatment of syphilis, but it cannot be said that the possibilities have been exhausted and it is to be hoped that experts in this particular field of chemistry will continue their efforts, especially in relation to the treatment of bacterial diseases.

Naturally enough, the organic arsenicals and especially arsphenamin and neoarsphenamin have also been tried, particularly in a clinical or empirical manner in the treatment of some bacterial diseases, since they quickly proved so efficacious in the treatment of spirochetic infections and since some biologists regard the organisms as closely related to the bacteria. But next to mercury probably the salts of silver have commanded most attention, and especially various organic compounds for the treatment of bacterial infections by local application. The salts of zinc have also been employed, the chlorid having been selected by Lister for this purpose in his pioneer work on the antiseptic treatment of wounds. Compounds of gold, copper, bismuth and some of the rarer metals have also been tried in experimental tuberculosis. Indeed, an extensive literature has accumulated upon these subjects, but it is hardly demanded that more than a fraction of it be reviewed or considered in this chapter in relation to the chemotherapy of bacterial infections in the modern sense.

Bacteriostatic and Bactericidal Activity of Compounds of Mercury, Silver, Arsenic, Tin, Zinc and Bismuth in Relation to Chemotherapy.—For example, a great deal of investigation has been devoted to a study of the bactericidal and bacteriostatic properties *in vitro* of a host of inorganic and organic compounds of mercury, arsenic, gold, copper, etc. The results are not without a certain value in relation to chemotherapy, but only in a broad and general manner, since it is well established that, in the presence of blood, exudates, etc., as encountered *in vivo*, bactericidal effects may be greatly reduced and that the organotropism or toxicity of the compounds for body cells may be sufficiently high to prevent their use in the practical treatment of bacterial diseases and especially systemic infections by intravenous administration of the compounds. Furthermore, the bacteriostatic and bactericidal properties described by different investigators are so greatly influenced by the technic employed and especially the menstrum, that only broad and general comparisons and deductions are warranted; likewise, the results vary according with the organism employed in the tests, and indeed, with different strains of the same organism, as I shall shortly discuss in a consideration of the important subject of selective bacteriostasis exhibited by mercury and other metals.

Without doubt the soluble salts of *mercury* are among the most potent, if not the most potent, known bacteriostatic and bactericidal agents *in vitro* in a menstrum of distilled water or simple saline solution. Even in a menstrum of blood, serum, pus or muscle extract, the majoriy of mercurial compounds maintain fairly high bactericidal values, so that they have long held the attention of chemotherapeutists in relation to the possibility of synthesizing useful compounds for the treatment of local and systemic bacterial infections.

It is hardly necessary, however, to pause here and discuss with much detail the bactericidal effects *in vitro* in water or saline solution of the salts of the heavy metals, because these effects are of value only in relation to the sterilization of instruments and other objects; in relation to the chemotherapy of localized and superficial infections of the skin, mucous membranes and wounds by local application or of systemic infections by subcutaneous or intravenous injection, as well as the disinfection of sputum, feces, urine, pus, etc., only the effects produced *in vitro* in the presence of blood, serum, or tissue extractives possess interest and practical importance. Possibly an exception may be made to this general statement in dealing with chemical agents primarily designed for treatment of localized infections of the urinary system in which useful tests *in vitro* may be conducted with a menstrum of sterile urine, as employed by Young, White and Swartz in their studies with mercurochrome.

I have selected a few compounds of the heavy metals for purposes of illustration in the present discussion because of their wide clinical use in the treatment of localized infections of mucous membranes and because in a general manner they serve as examples of the comparative bactericidal activities of the heavy metals represented by them. Working with the blood serum—muscle extract medium seeded with staphylococci and conducting duplicate tests in exactly the same manner and at the same time, except that sterile distilled water was substituted for this special medium, I have found that the *final* concentrations proving completely bactericidal at the end of twenty-four hours at 38°C. were approximately as follows:

Substances	Serum-muscle Medium	Water
Mercuric chlorid	1:1,600	1:1,250,000
Mercurophen	1:1,800	1:2,500,000
Mercurochrome	1: 200	1: 125,000
Silver nitrate	1: 200	1: 640,000
Argyrol	1: 20	1: 1,500
Protargol	1: 8	1: 1,500
Zinc chlorid	1: 80	1: 500
Arsphenamin (Disodium)	1: 60	1: 1,500
Neoarsphenamin	1: 20	1: 1,000
Dakin's solution	1: 8	1: 800
Boric acid	Not in 1: 40	1: 3,000

In other words, mercurophen or sodium oxy-mercuri-ortho-nitro phenolate, first described by Hantzsch and Auld[3] under the name of "merkurinitrophenole" but independently rediscovered and first biologically tested by Schamberg, Raiziss and myself,[4] is about twice as bactericidal for staphylococci and various other organisms in this medium as mercuric chlorid, while mercurochrome is about 8 times, silver nitrate about 8 times, argyrol about 80 times, protargol about 200 times, and zinc chlorid about 20 times, less bactericidal. It will be noted, however, that in a menstrum of distilled water the bactericidal values were all higher, but varying among the different compounds. Thus the bactericidal activity of mercurophen and mercurochrome was greatly reduced, but proportionately less in the blood-muscle extract medium than the other compounds tested, and they also produced less or no precipitation with the proteins and salts (phosphates) of the medium, which constitutes an advantageous property from the standpoint of chemo-

therapy. With a medium of sterile urine, Young and his associates observed that, whereas the silver proteins like argyrol and protargol in 1:1000 failed to kill *B. coli* or *Staphylococcus aureus* in one hour, mercurochrome killed both organisms in about one minute.

Examples of this kind could be multiplied at great length but with little advantage, since it is so well established that bactericidal activity of chemical agents *in vitro*, even in the presence of proteins, are of limited value in relation to chemotherapy, although of great value in relation to the sterilization of instruments and the disinfection of discharges and excreta. Thus the bactericidal activity of boric acid is a great deal less than that of the mercurials, but yet it constitutes a valuable agent for the treatment of local infections, as discussed in Chapter VIII.

From the standpoint of the treatment of systemic bacterial infections by intravenous administration of medicaments, the salts of only two of the heavy metals are of interest and importance, namely, mercurochrome and arsphenamin. It is true that mercuric chlorid and other inorganic and organic salts have been used from time to time, but none have produced the rather encouraging results observed during the past two years with mercurochrome. This compound is much less bactericidal *in vitro* than mercuric chlorid, mercurophen and many other compounds in both blood and saline media, probably at least 50 times less bactericidal for such organisms as the staphylococci and streptococci, because it undergoes dissociation so slowly, but this property also accounts for its greatly reduced toxicity *in vivo* which permits of the administration of relatively large amounts.

The bactericidal activity of *arsphenamin* and *neoarsphenamin in vitro* is discussed at more length elsewhere, but I may state here that contrary to popular impressions, they are not without some degree of bactericidal activity *in vitro* in both blood and saline media. But their bactericidal properties are relatively feeble, being at least 75 times less than that of mercuric chlorid.

But few of the salts of other heavy metals have been administered intravenously on a large scale for the treatment of systemic infections and their bactericidal effects *in vitro* are of chief interest only in relation to the treatment of localized infections. *Silver* compounds have been employed in some instances, but not on a large scale because of their toxicity and the danger of producing argyria. *Tin* and especially a mixture of chemically pure tin oxid and metallic tin known as "stannoxyl" has been advocated for the treatment of staphylococcus infections, but in my experience these compounds are but feebly bactericidal *in vitro;* 1:100 solutions or suspensions of stannous chlorid, stannic chlorid and stannic iodid in sterile water may kill *staphylococcus aureus* in less than five minutes but stannoxyl failed to do so in 60 minutes. In 1:1000 concentration all of these preparations failed to kill staphylococci in 60 minutes except a suspension of stannous chlorid which was bactericidal in 15 minutes. The tin preparations, therefore, do not command much interest from the standpoint of bactericidal activity *in vitro*.

The same may be stated of the *zinc* salts, although they have long been known to have antiseptic properties and the chlorid especially has been used by Lister, Kocher, and others. Its bactericidal activity, however, is far inferior to that of most mercury or silver salts.

Dakin and Dunham state that "the salts of *bismuth* do not appear to have been examined very carefully as regards their bactericidal action, although their action in checking undesirable fermentations in beer worts was discovered long ago. Most normal bismuth salts are more or less rapidly decomposed by water with formation of insoluble basic salts, and some of these have found effective use as mild antiseptics capable of slow but prolonged action."

Rapidity of Bactericidal Activity of Mercury and Other Metals.—But the matter of rapidity of disinfection by compounds of the metals is deserving of mention and especially when they are employed for the treatment of localized bacterial infections. For example, in the treatment of urethritis, conjunctivitis, gingivitis, etc., the disinfecting agent is in contact with the tissue for probably only a matter of a few seconds and only those agents known to act quickly are apt to prove bactericidal under these conditions. Of course, rapidity of sterilization bears a relation to concentration of the chemical agent and its absorption or fixation by cells, but comparisons may be made by working with similar concentrations under identical conditions. Mercurophen, for example, acts much more quickly than mercuric chlorid. Chick[5] found that *B. paratyphosus* could withstand the action of five per cent. bichlorid for four minutes, and *Staphylococcus aureus*, for fifteen minutes, if at once treated with a potassium sulphid antidote. Of course, the rapidity of disinfection is greatly reduced in a medium of blood, serum, muscle extract, etc.; under these conditions organisms may survive 1:3000 mercuric chlorid for several hours and, while numerous additional examples may be cited, the above will probably serve my present purpose which is merely to state that rapidity of disinfection in the presence of pus, blood, secretions, etc., bears an important and practical relation to the worthiness of any chemical agent proposed for the treatment of localized bacterial infections by topical application.

Acquired Resistance of Bacteria to Compounds of the Metals.—The subject of acquired resistance of bacteria to compounds of mercury and other metals has not commanded much attention. But it is not without considerable academic as well as practical interest, and especially in relation to the treatment of urethritis and other localized infections by the long continued application of the silver, zinc and other compounds.

Spiess and Feldt, in their series of studies upon the effects of gold compounds in tuberculosis, observed that tubercle bacilli may acquire resistance or fastness to gold cyanid *in vitro;* Shiga, however, found that tubercle bacilli do not develop a tolerance for gold and DeWitt and Sherman state that, in their experiments, tolerance developed so slowly as not to be an important factor in the treatment of tuberculosis in guinea-pigs with gold.

I have experimented with mercurial compounds and cultures of *Staphylococcus aureus* and *B. coli* with the general result that after a prolonged series of transfers the organisms could be rendered distinctly more resistant and the same is probably true of compounds of the heavy metals and most bacteria in general; but results *in vitro* are obtained only after several months of patient work and I doubt if bacteria, like the gonococcus, acquire sufficient resistance *in vivo* to the silver protein and other bactericidal agents materially to reduce the bactericidal effects of these compounds.

Selective Bacteriostatic Activity of Mercurial, Silver and Other Organic and Inorganic Compounds.—As stated in preceding chapters, many of the anilin dyes display a selective bacteriostasis and bactericidal activity *in vitro* and ethylhydrocuprein (optochin) and other cinchona derivatives are known to be especially destructive for pneumococci; the question naturally arises, do any of the organic and inorganic compounds of mercury and other heavy metals display a similar selective bacteriostosis *in vitro?* This question is one of considerable theoretical and some practical importance, since an ideal compound would be one possessing a wide range of pan-therapeutic activity suitable for the treatment of diseases produced by different organisms.

Selective Bacteriostasis of Mercurial Compounds.—Insofar as the ordinary organic and inorganic *mercurial compounds* are concerned, it is my observa-

tion that they do not exhibit any noteworthy evidences of selective bactericidal activities, except that, as a class, they are slightly more effective against Gram-positive than against Gram-negative organisms. But nearly all the organic and inorganic salts possess a high degree of bactericidal activity for practically all bacteria and some, like mercurochrome, for example, have been found to influence *B. coli* infections as well as those produced by staphylococci, streptococci and gonococci. It is true that some organisms are more readily and rapidly killed *in vitro* than others, but these variations are readily explained by factors other than selective bacteriostasis. But mercurophen, however, does display a certain degree of selective activity for the Gram-positive cocci (staphylococci, pneumococci and streptococci) and is likewise somewhat more active for Gram-positive bacilli (anthrax, subtilis, diphtheria and tubercle bacilli), but this selective bacteriostasis is not so specific or marked as shown by gentian-violet for Gram-positive organisms. All of the mercurials, and especially mercurophen, are likewise particularly bacteriostatic for spores like those of *B. anthracis* and *B. subtilis*. Mercurochrome is also somewhat more bactericidal for the Gram-positive staphylococcus than for the Gram-negative colon bacillus, and metaphen (4-nitro-3, 5-bisacetoxymercuri-2-cresol), recently described by Raiziss and Severac,[6] has similar properties. I may also mention that mercurophen and metaphen do not precipitate the dissolved proteins in blood and pus, do not form amalgams with ordinary surgical instruments and constitute very useful bactericides for the disinfection of sputum, urine, feces, pus, etc., being particularly valuable for the rapid sterilization of instruments.

It may be stated, therefore, that while all of the mercurials possess some degree of selective bacteriostasis for staphylococci and other Gram-positive cocci, this property is especially well marked with mercurophen and metaphen and to some extent with mercurochrome. DeWitt[7] has observed that these compounds also display a high bactericidal activity for tubercle bacilli.

DeWitt[8] has also studied the inhibitory effects of a large number of other new organic compounds of mercury which lead to some interesting deductions on the chemistry of these substances in relation to tuberculocidal effects, to which I shall shortly refer in more detail.

Selective Bacteriostasis of Silver Compounds.—The silver salts, however, appear to be somewhat more selective for the Gram-negative cocci and especially the gonococcus, as recently observed by Hamilton,[9] with silvol, neosilvol and similar metallic silver colloids working with a modification of the U. S. Hygienic Laboratory method. According to Chick, the action of silver nitrate on *B. paratyphosus* is similar to that of mercuric chlorid, although silver cyanids, colloidal silver, and various organic compounds which yield few silver ions on solution in water, appear to have inferior bactericidal properties. Argyrol is at least ten times less bactericidal than silver nitrate, since, in a final 5 per cent. concentration in a medium of blood serum and muscle extract, it failed to sterilize completely in six hours, whereas a final concentration of 0.3 per cent. silver nitrate kills off about 95-per cent. of staphylococci and other organisms in this period. Smith[10] tested the effect of a double salt of methylene-blue and silver nitrate on inhibition of growth of human tubercle bacilli on broth cultures and also as a chemotherapeutic agent in experimental tuberculosis in guinea-pigs, and observed complete inhibition in dilution of 1:100,000; but its chemotherapeutic action was negligible. DeWitt and Sherman[11] have also investigated the tuberculocidal properties of silver nitrate and combinations with trypan-blue, but without observing noteworthy effects.

Selective Bacteriostasis of Compounds of Copper, Gold, Tin, Zinc, Arsenic and Iodin.—Insofar as *compounds* of *copper and gold* are concerned, most attention has been devoted to their effects upon tubercle bacilli and it may be that they possess in slight degree some selective effects for these organisms. But compounds of copper and gold are as a whole relatively feeble bactericides and especially in comparison with the compounds of mercury. Copper compounds do not display any particular selective bacteriostatic properties unless it be for typhoid and Gram-negative bacilli in water in the absence of excessive amounts of organic matter, being about one-half as bactericidal as mercuric chlorid; copper sulphate, however, does possess a remarkable affinity for many species of algae, being capable of destroying them in water in 1:1,000,000 dilution.

Compounds of *gold* have always held a place of interest in relation to the chemotherapy of tuberculosis since Koch,[12] in 1890, observed that the cyanid completely inhibited the growth of tubercle bacilli in dilutions of 1:2,000,000, although it was entirely without curative effects in experimental tuberculosis of guinea-pigs. Since then a large number of new gold compounds have been tried in the treatment of tuberculosis of the lower animals and human beings, but here it may be stated that DeWitt and Sherman found that 1:1000 gold chlorid was required to kill tubercle bacilli *in vitro* and that even 1:100 of the tricyanid was not always able to kill all of the organisms, although 1:2,000,000 of the cyanid proved bacteriostatic, as stated by Koch.

Apparently compounds of *tin* and *zinc* have not been studied from the standpoint of selective bacteriostasis, but, according to the results of my own limited studies, the ordinary inorganic salts do not display any evidences of this property except that they are slightly more effective against the Gram-positive cocci like staphylococci, streptococci and pneumococci than against Gram-negative bacilli like *B. coli communis* and *B. typhosus*.

Various organic compounds of *arsenic* have long been used in the treatment of bacterial infections, but more for their possible dynamogenic than bactericidal effects. As previously mentioned, arsphenamin and neoarsphenamin display feeble bactericidal activities *in vitro* in water or saline solutions and possibly these compounds are somewhat more bactericidal for streptococci than staphylococci, but the differences are only slight and easily accounted for by other factors. The investigations of Douglas and Colebrook and Allison show that these compounds are bactericidal *in vitro* and apparently may raise the bactericidal activity of the blood for a few hours after the intravenous injection of large doses; this is particularly true of neoarsphenamin, but apparently less marked with arsphenamin and almost absent with sodium cacodylate, although the latter compound has been reported by Bargen as distinctly curative in experimental streptococcus infections of rabbits.

Iodin and compounds of iodin are worthy of brief mention in relation to tuberculosis, since they have been long advocated by some physicians in the treatment of this disease. Cantani[13] has stated that iodin in concentration of 1:500 to 1:1000 exerted some bacteriostatic effect upon tubercle bacilli, but DeWitt and Sherman found that Lugol's solution had very little bactericidal activity, since in full strength the solution was unable to kill all bacilli. Tincture of iodin has a well marked bactericidal effect upon staphylococci and streptococci, accounting for its popularity as a disinfectant of the skin and for the treatment of bacterial infections by local application, but its effects *in vivo* are very much reduced; to the best of my knowledge it does not display any particular selective bacteriostasis and certainly not for *Sp. pallida* or *B. tuberculosis*.

Selective Bacteriostasis of Creosote, Guaiacol and Their Derivatives.—It is necessary to refer briefly to the bacteriostatic and bactericidal activity of these compounds in relation to the chemotherapy of tuberculosis of the lungs, since they have long held a place of interest in the treatment of not only this disease but also in the treatment of non-tuberculous bronchitis; furthermore the question of their possible specific bactericidal effects for tubercle bacilli, as well as for the organisms of simple bronchitis and secondary infection of tuberculous tissues, such as streptococci, staphylococci, pneumococci, etc., becomes one of importance in relation to chemotherapy. I may state that Ehrlich was impressed with the possibilities of improving creosote therapy and with the assistance of Bechhold prepared a series of new compounds and added very materially to our knowledge of the chemistry of these substances in relation to their bactericidal activity, to which I will later refer. DeWitt, Suyenaga and Wells[14] have exhaustively reviewed the literature on this subject of bactericidal activity of these compounds *in vitro* and *in vivo* and have likewise contributed a thorough study of the subject themselves, so that it may suffice to quote here from their conclusions. They state that "despite the extensive use of creosote and related compounds in the treatment of tuberculosis, practically no evidence exists as to the susceptibility of *B. tuberculosis* to antiseptics of this class, or as to their influence on the course of tuberculosis in experimental animals."

Selective Bacteriostasis of Chaulmoogra Oil and Derivatives.—Interest in the possible selective bacteriostasis of *chaulmoogra oil* and its derivatives for acid-fast bacilli, and particularly *B. tuberculosis*, has been stimulated by the reports of Heiser and others concerning the curative properties of these substances in leprosy. In 1915, Hernandez[15] reported that the addition of 2-per cent. chaulmoogra oil to culture mediums inhibited the growth of tubercle bacilli and had a favorable influence on tuberculosis in a few patients. Walker and Sweeny[16] have reported that the sodium salts of the total fatty acids of chaulmoogra oil (chaulmoogrates) possess an extremely high bactericidal and bacteriostatic activity for the tubercle bacillus *in vitro*. The authors also give a complete review of the literature and a description of the chemistry of chaulmoogra oil. At about the same time Davis, Jager and I[17] were experimenting with oil expressed cold from seeds of *Taraktogenous kurzii* and bovine tubercle virulent from guinea pigs. Since the oil was immiscible with the medium, a special technic was required for determining its possible germicidal activity for the tubercle bacillus.

Our experiments were entirely negative; even pure undiluted chaulmoogra oil failed to kill all of the tubercle bacilli and the results are in striking contrast to those of Walker and Sweeney, but our work was conducted with the whole oil, while they employed the soluble sodium salts of the total fatty acids. Out next experiments were made with what may be called a combined *in vivo-in-vitro* technic, aiming to bring the oil into more intimate contact with the bacilli and testing for germicidal activity by injecting the mixtures into guinea-pigs. This method was rather favorable to any germicidal activity of the oil, as it was brought into close contact with the bacilli for eighteen hours at room temperature. The number of bacilli was not large and the dose injected into the pigs required 5 to 6 weeks to produce well marked inguinal adenitis and infection of the spleen and abdominal glands. However, even if but few bacilli escaped destruction, the results of inoculation into the guinea-pigs would probably produce tuberculosis; therefore, these experiments have shown the absence of complete bactericidal activity, but have yielded no information on the question of partial destruction of the bacilli. While I shall later refer to the results of additional experiments

which we conducted on the treatment of experimental tuberculosis of guinea-pigs with chaulmoogra oil, I may state here that our results were completely negative.

Bactericidal Activity of Hexamethylenetetramin and the Selective Bacteriostasis of Its Quaternary Salts.—Since the recognition in 1894 of *hexamethylamin* as a beneficial substance in the treatment of bladder infections, it has been recommended as an antiseptic agent for virtually all the body fluids, largely on the basis of the fact that after internal administration the drug may be found present everywhere in the body. To this circumstance is added the advantageous feature that hexamethylenamin is practically non-toxic. It is an established fact, however, that this substance as such is not bactericidal, since Hanzlik and Collins[18] clearly demonstrated that bacterial growth is not prevented by it, even in proportions much higher than could obtain anywhere in the body, and that the administration of hexamethylenamin could not be expected to exert a marked antiseptic effect in the tissues, although a partial restraining action was not excluded. In an acid solution, hexamethylenamin disintegrates into ammonia and formaldehyd. The latter substance is admittedly bactericidal and to it doubtless are due the beneficial therapeutic results experienced in the treatment of urinary infections; for the urine usually develops an acidity favorable to the desired reaction, liberating formaldehyd. The latest effort, by De Eds,[19] to discover an unsuspected comparable change in the migration of hexamethylenamin through the blood and tissues has yielded only negative results. Jacobs, Heidelberger, Amoss and Bull,[20] however, have thought it worth while to synthesize new compounds of hexamethylamin and they have studied these with particular care for evidences of selective bacteriostasis for *B. typhosus*, streptococcus, meningococcus, and gonococcus with some striking instances of partial specificity. A particularly valuable outcome of their work has been to secure new information bearing upon the important question of chemical constitution of the quaternary salts of hexamethylamin to disinfectant activity *in vitro*.

Bactericidal Activity of the Blood and Urine after the Administration of Mercurial and Arsenical Compounds.—The effect of compounds of mercury and other metals in the treatment of experimentally produced bacterial infections may be now considered, but before taking up a consideration of this important subject, it will be profitable to inquire whether the administration of these substances to the lower animals appreciably raises the bactericidal activity of the blood; furthermore, the matter of rendering the urine bactericidal is also of interest and importance and especially in reference to the treatment of infections of the urinary system.

Schamberg, Raiziss and I[21] have observed that the intravenous injection of mercurophen into rabbits in sublethal amounts (0.0015 gm. per kilo) was found to increase appreciably the bactericidal activity of the blood during the first few hours for staphylococci, pneumococci and *B. typhosus*, whereas the administration of mercuric chlorid and other mercurial compounds usually failed to increase to the same degree the bactericidal activity of the whole blood of rabbits for these microorganisms. Similar results were observed by Borow and myself[22] employing the Heist-Lacy method.

Hill and Colston[23] have observed that, after the intravenous administration of mercurochrome to normal rabbits, the urine became either bactericidal or strongly bacteriostatic for *B. coli*. This inhibitive action was strongest during the first five hours after injection. The same authors[24] have shown that, after the intravenous administration of mercurochrome to normal

rabbits, the blood is strongly bacteriostatic for *B. coli* from fifteen to forty-five minutes after injection.

The results of these investigations have indicated, therefore, that it is possible to administer sufficient amounts of some of the new mercurial compounds, and especially mercurochrome, to appreciably raise the bactericidal effects of the blood. It is true that these effects are of short duration because of rapid elimination and fixation of the compounds by the tissues, but yet it is sufficient to lend considerable basis for the hope that it may be possible to appreciably reduce the degree of a bacteremia or dissipate it entirely by the intravenous injection of large but comparatively safe doses of these compounds; in fact, the results of animal experiments have shown that this may occur in at least some instances.

I have already referred to the bactericidal activity of arsphenamin and neoarsphenamin *in vitro* in water or saline solution. Douglas and Colebrook[25] state that the bactericidal activity is reduced in the presence of serum or blood. They also reported that the intravenous injection of neoarphenamin in ordinary doses raises the bactericidal activity of the blood which reaches a maximum in one hour and rapidly diminishing in three or four hours. Curiously arsphenamin in ordinary dosage was reported as being without these effects, but the authors suggest that neoarsphenamin may be of value in the treatment of bacterial infections, an opinion which later induced Allison to employ these compounds in experimental streptococcus bacteremias of rabbits.

Compounds of Mercury, Arsenic, Gold, Copper, Iodin, and Other Substances in the Chemotherapy of Experimental Tuberculosis.—With this review of the bactericidal effects of compounds of mercury, arsenic and other metals *in vitro* and in relation to the bactericidal properties of the blood *in vivo*, their influence upon experimental bacterial infections of the lower animals may now be considered. I may state at once that the results have been largely disappointing and of a negative character, but yet within the past few years some compounds belonging to this class have yielded encouraging results.

Since tuberculosis was one of the first diseases to be produced experimentally and since the disease is so readily induced in guinea-pigs, it is no wonder that the major portion of experimental work in chemotherapy with mercury and other metals was conducted with this infection since Koch's and Cornet's original experiments in 1890, the former reporting that mercury in vapor form was entirely without influence on the progress of the disease in animals and the latter observing that mercuric chlorid, administered to guinea-pigs to the point of toxic effects followed by inoculation with living bacilli, had no appreciable curative influence when compared with the induced disease in control animals which were not mercurialized.[26]

Mercurial Compounds in the Chemotherapy of Experimental Tuberculosis.—Insofar as the ordinary and well-known organic and inorganic *salts of mercury* are concerned, it may be stated that none have shown any appreciable curative effects upon tuberculosis produced in guinea-pigs. In 1914, DeWitt[27] found that an insoluble mercury-trypan-blue had some influence upon the disease, since the treated animals lived longer than the controls although the compound was quite toxic. In a subsequent study DeWitt[28] employed a large number of new compounds in the treatment of experimental tuberculosis of guinea-pigs, with practically negative results. Later DeWitt[29] used mercurophen and mercurochrome in the treatment of guinea-pigs inoculated with tuberculosis, with the general result that these compounds seemed to delay considerably the development of the disease; but marked generalized

tuberculosis occurred in all the animals that lived long enough. Of interest in this connection are the results of Corper's experiments with dogs indicating that mercurochrome in one-half to two per cent. solution should not be injected into tuberculosis cavities or into the pleural spaces in the treatment of tuberculosis or other infections because of the extensive tissue changes produced, largely in the nature of hemorrhagic pneumonitis with focal abscesses and terminating in proliferative pneumonitis.

Arsenical Compounds in the Chemotherapy of Experimental Tuberculosis.—Although *arsenic* has long been advocated as beneficial in the treatment of tuberculosis, Arken and Corper[30] concluded in 1916, after a review of the literature, that it had not been demonstrated to have any specific action and that its value in this disease can be attributed only to its favorable effects on metabolism. These investigators also studied the effects of sodium arsenite, sodium cacodylate, mercury cacodylate, atoxyl, arsacetin and neosalvarsan in the treatment of inoculated animals, with negative results.

Gold Compounds in the Chemotherapy of Experimental Tuberculosis.—Probably no compounds of the heavy metals have commanded as much attention in the treatment of tuberculosis as the *salts of gold;* indeed, quite a large literature has accumulated upon the subject insofar as the treatment of tuberuclosis of human beings is concerned, which is reviewed in Chapter VIII, but here it may be stated that relatively few experiments have been conducted with experimental tuberculosis of the lower animals and the results of these have been largely of a negative character. Koch, in 1890, observed that the gold salts then available had no beneficial effects in tuberculous animals, but interest in these compounds was greatly renewed by Spiess and Feldt[31] who, together or separately, between 1912 and 1916, published a series of papers on the subject. These authors found that gold cyanid and gold potassium cyanid were too toxic for use in human patients, but, as cantharidin had earlier been found to have a marked affinity for tuberculosis tissues, they conceived the idea of reducing the toxicity of the cantharidin and using it as a carrier for the specific gold cyanid; apparently they were able to reduce the toxicity of the cantharidin without altering its affinity for tubercles by condensing it with ethylenediamin. This compound was quite nontoxic and combined readily with gold cyanid. They used first the auric salts, but finding them less efficacious than the aurous salt, employed mono-canthatidyl-ethylene-diamin-aurous-cyanid under the name "aurocantan" or "canthoridyl."

This compound was first tested on about 100 animals during 1½ years and was then used on human patients. They claim that its beneficial effects are due partly to a direct inhibitory action on the tubercle bacilli and partly to an indirect action on the defensive agencies of the body believing that it simulates connective tissue formation and destroys disease products by its oxidizing power. In experimental tuberculosis in animals, they claim that weight was increased and life was prolonged.

But a number of other investigators found none or much less beneficial effects than those reported, and Pekanovitch,[32] Hauck,[33] Gelpe[34] and others have directed attention to the dangers attending the use of "aurocantan" from the destruction of erythrocytes and hemorrhages with the production of jaundice and anemia. Furthermore, DeWitt, Cadwell and Leavell,[35] in a series of studies employing "aurocantan" and the simple gold cyanids, observed that gold was deposited in the various organs of experimental animals including tuberculous tissue, but without appreciable curative effects. Indeed, the amounts found in the liver, spleen, lungs and other sites favored by tubercle formation were many times the concentration necessary in the

test-tube completely to inhibit growth of the bacillus, but yet excited no restraining influence upon the disease.

At this writing a new gold compound designated as "sanocrysin" and produced by Møllgaard in Copenhagen is attracting considerable attention in the treatment of tuberculosis. Møllgaard states that no reaction follows the introduction into the body of this remedy by the intravenous method, provided the tissues are healthy; but if they are tuberculous, a violent reaction ensues. It is assumed that the reaction is the result of release of toxic substances from tubercle bacilli that are destroyed by the remedy. The reaction is opposed by the injection of a specially prepared horse serum which, Møllgaard believes, has greatly reduced the severity of the phenomena of the reaction. Møllgaard has described the complete clinical recovery of two monkeys with severe tuberculous infection, following the use of his method and several well-known Danish clinicians have reported brilliant results in the cases of many patients. However, there were several instances in which death had followed the administration of the remedy, presumable on account of difficulty in determining accurately the proper dosage, and a final opinion of its value cannot now be expressed. I may state however, that at the present writing the results of carefully conducted experiments in the Hygienic Laboratory by a commission composed of Theobald Smith, W. H. Park and E. C. Schroeder have failed to demonstrate any marked degrees of curative activity by this compound. From our knowledge of the action of gold compounds in general in tuberculosis, I rather surmise that the toxic reaction produced by "sanocrysin" is due to foci poisons from the lesions engendered by the tuberculin-like reaction of hyperemia, exudation and enhanced cellular necrosis; possibly any curative effects it may possess are likewise similar to those produced by these tuberculin-like reactions favoring the laying down of fibrous tissue and without involving the question of direct and marked tuberculocidal properties of the compound itself.

Copper Compounds in the Chemotherapy of Experimental Tuberculosis.—*Copper* is another metal which has attracted considerable attention in the treatment of tuberculosis, especially of human beings, but without much support from the standpoint of their effects in experimental infections. DeWitt[36] found that copper trypan-blue did not penetrate either normal or tuberculous tissues, and that it is probably changed to an insoluble form or a suspension colloid and retained at the point of injection. Von Linden,[37] however, believes that copper is bound by the fatty acids of tubercle bacilli and that tuberculosis of guinea-pigs treated with copper shows a more chronic course than untreated controls, with the complete checking of the disease when large initial doses (3 to 5 mgm. of copper) are given. Other investigators, however, have not been able to confirm these results, among them being Selter,[38] who was associated with V. Linden, and who states that there was none or but very little favorable influence of copper on tuberculosis and none that could be called specific for the disease. Corper,[39] who has reviewed this literature up to 1912, made a very careful study of the absorption, distribution and curative activity of copper compounds in tuberculous guinea-pigs and rabbits, finding that they are distributed not as salts but in colloidal form and that they do not usually penetrate tubercles or appreciably influence the disease. Koga,[40] however, working with a combination of two parts of potassium cyanid and one part of copper cyanate, the mixture being designated as "cyanocuprol," reported good results in the treatment of tuberculosis of guinea-pigs. This compound has been extensively used in Japan and with apparently good results in some cases, but it is now the consensus of opinion that the effects are not specific but due to the focal

tuberculin-like reactions which may be produced; in my experiments employing infected guinea-pigs treated with cyanocuprol sent to me by Koga, the results were almost negative, only an occasional animal surviving long enough after the death of the controls or showing a sufficiently milder course of the disease, to justify the conclusion that some slight beneficial effects may have been produced. No doubt copper compounds may favorably influence tuberculosis, but this appears to be non-specific and the result of some radicle of the compound other than copper itself producing hyperemia and inflammation exciting effects about the tubercles similar to the effects of tuberculin.

Iodin in the Chemotherapy of Experimental Tuberculosis.—Iodin and iodin preparations have also long held a place of interest in the treatment of tuberculosis. But iodin has but a feeble bactericidal action on tubercle bacilli and little is to be expected from the standpoint of specific tuberculocidal effects *in vivo*. However, it is possible that iodin may serve as a carrier of more potent chemical antiseptics into tubercles and in truth the substance has commanded most attention from this aspect in the modern chemotherapeutic investigations in tuberculosis. In 1907, Loeb[41] and Loeb and Michaud[42] reported that tuberculous tissue took up a disproportionately large amount of iodin administered as potassium iodid and Wells and Hedenburg,[43] after an exhaustive study of this subject in 1912, were able to confirm these findings but showed that the process was not specific since other necrotic tissues also took up more iodin than normal tissues. The explanation offered was that normal cells are not perfectly permeable to iodids (except perhaps kidney cells) and lose this impermeability or semipermeability when killed or injured, thus becoming entirely permeable for crystalloids present in the surrounding fluids. No evidence could be found of any tendency for iodin compounds of whatever nature to accumulate in tubercles or other necrotic areas, or to persist in such areas when disappearing from the normal tissues and the blood. Exudates contained approximately the same proportion of iodin as the blood of the same animals, and hence any area with inflammatory edema and congestion will commonly show more iodin than normal tissues, although not usually more than the blood.

While several investigators have claimed that the daily administration of potassium iodid increases absorption and the organization of tuberculous nodules, these claims have not been confirmed and, indeed, Hirsch[44] and others have concluded that the use of iodin and iodids for facilitating the absorption of necrotic material and promoting the organization of tuberculous and other granulation tissue has no experimental support. As stated by DeWitt, iodin as a chemotherapeutic agent has as yet given little proof of its value or encouragement for the hope that it may prove of real value in the chemotherapy of tuberculosis.

Cerium, and Other Rare Earths in the Chemotherapy of Experimental Tuberculosis.—At the present writing the salts of *cerium, samarium, neodymium, praseodymium and other rare metals* are commanding considerable attention in the chemotherapy of tuberculosis and especially by French physicians. Grenet and Frouin,[45] for example, state that it has been established that the salts of cerium reduce the fats of the tubercle bacillus from 25 to 40 per cent. to 22 to 16 per cent. in cultures to which the salts are added, and that these salts induce an increase of lymphocytes both in men and animals, but that some are too toxic for clinical use. Renon[46] goes so far as to state that "the results obtained by Grenet and Frouin with the sulphates of the cerium earths are the most scientific yet realized in the chemotherapy of tuberculosis." Beneficial effects have been claimed in tuberculous patients and guinea-pigs which they ascribe to an effect upon the bacillus as well

as by favoring sclerosis of tubercles on account of the enormous mononuclear leukocytosis induced. They have not claimed complete cures, however, and insist that the salts must be used only in afebrile cases of pulmonary tuberculosis. Frouin[47] states that rabbits and guinea-pigs inoculated with virulent bovine tubercle bacilli and treated with intraperitoneal injections of sulphates of cerium earths, have shown sclerosis of the lesions and with few exceptions have lived from two to five months longer than the controls but DeWitt[48] has recently stated that the experimental observations on the cerium earth group do not warrant the amount of clinical enthusiasm that has been reported.

Creosote, Guaiacol, and Their Derivatives in the Chemotherapy of Experimental Tuberculosis.—The results of bacteriostatic and bactericidal tests *in vitro* for human and bovine tubercle bacilli employing *creosote, guaiacol and their derivatives*, have not given much or any hope for specific bactericidal effects *in vivo* and the results of animal tests have been generally a negative character as shown by the review of the literature by DeWitt and her colleagues[49] of these compounds as well as the "thiocols" and other derivatives. They also made therapeutic tests employing guinea-pigs injected subcutaneously with two strains of human tubercle bacilli, one highly virulent and the other much less so and failed to observe any beneficial therapeutic effect on tuberculous guinea-pigs, which, in view of the low bactericidal power of the substances test was to be expected. As stated by them it does not mean that these substances may not have value in open tuberculous infections of man in which other bacteria than *B. tuberculosis* are involved, but it does substantiate the opinion that seems to have been generally reached by careful clinical observers, that creosote and guaiacol do not have a specific action on tuberculous infection.

Chaulmoogra Oil and Its Derivatives in the Chemotherapy of Experimental Tuberculosis.—As previously stated, Davis, Jager and myself found that undiluted and diluted *chaulmoogra oil* had no appreciable bactericidal effect on virulent tubercle bacilli as determined by an *in vitro-in-vivo* method employing guinea pigs. In doses of 0.2 c.c. per 100 gm. of body weight administered by intramuscular injection at weekly intervals (equivalent to 2 c.c. per kilo or 120 c.c. per 60 kilos) it had none or but slight effect on the course of tuberculosis in infected guinea-pigs. The oil was found, however, to be relatively non-toxic for guinea-pigs; animals have borne at least 11 intramuscular injections of 0.2 c.c. per 100 gm. without deleterious effect except localized inflammatory changes at the sites of injections.

Walker and Sweeney, however, have reported that the fatty acids of the chaulmoogric series, chaulmoogric and hydnocarpic acids and possibly lower isomers of this series may have some curative effects in experimental tuberculosis of rabbits and guinea-pigs since the average duration of life of the treated animals was greater than that of the untreated controls. Culpepper and Ableson[50] also reported some beneficial effects in the treatment of tuberculous guinea-pigs with the acid sodium salts of the esters of chaulmoogra oil, but Voegtlin, Smith and Johnson[51] after exhaustive tests with chaulmoogra oil, chaulmoogric acid, and ethyl esters and iodin saturated ethylchaulmoograte in guinea-pigs inoculated with a virulent strain of human tubercle bacilli, reached the conclusion that these substances had no influence upon experimental tuberculosis. Finally, Walker has reported that he was unable to find chaulmoogra oil and its fatty acids in the tubercles of treated animals and he considered this failure to penetrate tuberculous tissues the cause of the negative results in the treatment of the disease with these substances.

Cinnamic Acid and the Cinnamates, Bile and the Bile Salts, Fats and Fatty Acids and Various Hydrocarbons in the Chemotherapy of Experimental Tuberculosis.—Finally, brief mention may be made of *cinnamic acid* and *sodium cinnamate* in the treatment of experimental tuberculosis since, as early as 1893, Landerer[52] claimed that the former caused a marked increase of leukocytes around tubercles in animals; Hacobson[53] states that the same effects were produced by *ethyl cinnamate* along with a shortening of the thermal reaction time following injections of tuberculin. Corper[54] however, found that *sodium cinnamate* was too hemolytic and toxic for the treatment of tuberculosis.

In 1909, Deycke and Much[55] reported that tubercle bacilli suspended in 25 per cent., solutions of *cholin* underwent partial bacteriolysis with a complete solution of the fatty material with loss of the Gram staining power; on this basis, Mehler and Ascher[56] tried "*borcholin*," a cleavage product of cholin, and reported that it possessed tuberculocidal activity *in vitro* and was well borne by animals by intravenous injection, but with little or no effect in the treatment of tuberculosis. It was hoped, however, that "borcholin" might serve as a carrier of more active agents and success was claimed in the healing of tuberculous lesions by combining it with copper; Mayer[57] states that a combination with gold potassium cyanid apparently aided the curative properties of the latter.

More recently Takeoka,[58] drawing attention to numerous reports in literature indicating that the liver may be actively concerned in the destruction of tubercle bacilli and other organisms *in vivo*, tried the effects of *taurin*, the most characteristic animo-acid of the bile, in dose of 0.05 to 0.1 gm. in the treatment of experimental tuberculosis of guinea-pigs and rabbits. Taurin was also used in combination with a colloidal mixture of sodium gold chlorid and sodium oleate, but equally good results were observed with the taurin alone. It was claimed that in nearly every instance the untreated controls died before any of the treated animals and that in some instances apparent cures were brought about. This work, however, has not yet been confirmed and verification is required before one may accept the conclusion that bile or bile salts have a marked therapeutic value in experimental tuberculosis, and especially since the liver may be extensively involved in tuberculous infection, indicating that the bile frequently fails to inhibit the disease in both human beings and the lower animals.

This naturally brings up the question of the curative activity of the *fats and fatty acids* in tuberculosis, and especially cod liver oil, which deservedly occupies a useful place in the treatment of the disease and especially of the surgical forms. Miller[59] states that sperm oil added to media on which tubercle bacilli were being grown caused rapid bacteriolytic changes and DeWitt has confirmed these observations. The salts of the fatty acids, however, are lacking in beneficial effects in tuberculosis suggesting that the whole oil may owe its curative properties to vitamins which bring about an accelerated rate of re-calcification and an increase of inorganic phosphorous in the blood in both rickets and tuberculosis in much the same manner as heliotherapy, without involving the question of specific tuberculocidal action from the oil which is doubtless a very remote and improbable effect.

Compounds of Arsenic, Mercury and Other Substances in the Chemotherapy of Experimental Streptococcus, Pneumococcus, Staphylococcus, Anthrax and Other Infections.—Much less investigation has been devoted to the subject of the chemotherapy of experimental pneumococcus, streptococcus, staphylococcus and other bacterial infections with compounds of the metals, although this is a very important field worthy of intensive study

because of the frequency and highly fatal character of these diseases. I have reason to believe, however, that much more work has been done than is to be found in the literature because of the hesitation in recording negative results. This has certainly been true of Schamberg, Raiziss and I who have worked with the mercurials and arsenicals in experimental bacterial infections off and on for more than six years but delaying in reporting our work because of the negative and disappointing character of the results.

I am inclined to believe that much of this has been due to the unnecessary severity of our experimental infections; for example, streptococcus and pneumococcus infections induced in mice and rabbits have usually killed in 48 hours and it would require a very powerful agent indeed to prolong life or cure the infection under such conditions. I mention these circumstances at present only to re-emphasize what was stated in Chapter III, that compounds failing to materially influence such acute virulent experimental infections may yet prove beneficial and useful in the treatment of the less severe and fulminating infections of human beings.

While a large number of compounds have been tried out in the treatment of experimental tuberculosis, as just reviewed in the preceding section, relatively few have been employed in the various infections now under discussion. Indeed, only the new organic arsenicals like arsphenamin and neoarsphenamin, some of the new mercurials like mercurophen and mercurochrome, and the hexamethylamin and a few other compounds need to be considered.

Arsphenamin and Other Arsenicals in the Chemotherapy of Experimental Systemic Streptococcus Infections.—In 1918, Allison,[60] influenced by the report of Douglas and Colebrook on the bactericidal activity of arsephenamin and neoarsphenamin *in vitro*, as well as from the standpoint of temporarily raising the bactericidal activity of the blood following intravenous injections of ordinary doses, undertook a study of the bactericidal effects of *arsphenamin in vitro* and in the treatment of streptococcus infections of rabbits. Allison employed two different strains of streptococci and found that he was able to save about 70 per cent. of infected rabbits with intravenous injections of three different brands of arsphenamin as against a survival of about 40 per cent. among untreated controls. In more acute virulent infections, however, the componds were without effect, but Allison expressed the belief that the treatment may be successful in human infections if the source of infection could be removed or drained and the injections given before secondary localization occured.

During the past four years I have conducted a large number of tests with the assistance of Dr. Malcolm J. Harkins. Rabbits and mice were employed, the former being infected by intravenous injections of streptococci and the latter by subcutaneous injections according to Morgenroth's method. Several different strains of streptococci were used, varying greatly in virulence for these animals. *Arsphenamin* and *neoarsphenamin* were administered by intravenous injection to rabbits and by intraperitoneal injection to mice, the doses being 0.010 gm. of the former and 0.015 gm. of the latter, per kilo of weight. The first dose of each drug was given four hours after inoculation and subsequent doses at daily intervals. Blood cultures were made of the rabbits during life and of all animals after death; numerous untreated controls were always included. The results have varied according to the virulence and severity of the infection. In acute fulminating infections with positive blood cultures ending fatally in four days or less, we have never been successful in sterilizing the blood or appreciably prolonging life. In less virulent infections and especially among mice, both arsphenamin and

neoarsphenamin have prolonged the lives of a small percentage of animals, although in no case in which streptococci were found in the blood stream. I believe, therefore, that arsphenamin and neoarsphenamin may exert an appreciable but relatively feeble curative effect upon experimental streptococcus infections, but that these effects are not appreciable in the presence of infections sufficiently virulent to maintain the organisms in the blood.

I have also experimented with *sodium cacodylate* in the same manner, because of the reports bearing upon its use in the treatment of streptococcus endocarditis, but in my experience the compound has proved without appreciable effect in doses as high as 0.005 gm. per kilo (corresponding to 5 grains per 60 kilos) by administration according to the above plan.

Arsphenamin and Neoarsphenamin in the Chemotherapy of Experimental Anthrax.—Probably no bacterial infection has attracted as much attention as *anthrax from the standpoint of treatment with arsphenamin and neoarsphenamin;* quite a large literature has accumulated upon the subject most of it dealing with the results observed in the treatment of infections of human beings. Schuster,[61] observed in 1912 that rabbits inoculated subcutaneously with lethal amounts of anthrax culture could be saved if arsphenamin in dose of 0.04 gm. per kilo was given within the following 12 hours; smaller doses were generally ineffective. Bierbaum[62] reported that, if arsphenamin in dose of 0.1 gm. per kilo by subcutaneous injection was given to guinea-pigs immediately after inoculation with anthrax bacilli, the majority survived; but if treatment was delayed for two to four hours, the majority perished of anthrax bacteremia. Better results were observed with a combination of arsphenamin and anti-anthrax serum. Isabolinsky[63] has also reported that arsphenamin in dose of 0.06 gm. per kilo apparently protected rabbits against lethal anthrax injection when the treatment was given not later than two hours after inoculation. When the drug was combined with anti-anthrax serum the results were more marked, since animals could be saved up to seven hours after injection.

During the past six years, I frequently experimented with arsphenamin and neoarsphenamin in the treatment of mice, guinea-pigs and rabbits inoculated with virulent anthrax bacilli, but with generally unsatisfactory results largely due to the difficulty of gauging the correct amount of culture to employ. The anthrax bacillus in my experience has proved one of the most difficult to manage from this standpoint, since it is subject to rather wide and unexpected changes in virulence for the lower animals. In my experiments, arsphenamin and neoarsphenamin were administered four and two hours before inoculation, simultaneously with inoculation and two, four and twenty-four hours after inoculation. In a general manner, it may be stated that arsphenamin in dose of 0.02 gm. per kilo and neoarsphenamin in dose of 0.03 gm. per kilo have saved some animals when given two hours before or within two hours after inoculation with approximately ten times the minimal lethal dose of culture. Smaller doses of the drug were generally without effect; larger doses actually gave poorer results probably because of a lowering or resistance by the toxic effects of the drugs. Treatment four hours before inoculation sometimes saved the animals; in most instances, however, it failed; treatment four hours or longer after inoculation usually failed to prolong life. I believe it may be stated, therefore, that arsphenamin and neoarsphenamin, especially the former, possess in slight degree an appreciable bactericidal activity for the anthrax bacillus *in vivo,* but the curative effects are so feeble that it is doubtful if these compounds are capable of favorably influencing anthrax bacteremias in man.

Mercurial and Arsenical Compounds in the Chemotherapy of Experimental Systemic Pneumococcus Infections.—Owing to the high bacteriostatic and bactericidal activity of *mercurophen* for pneumococci *in vitro*, Schamberg, Raiziss and I[64] tried out its curative activity *in vivo* employing since inoculated with amounts of virulent Type I pneumococci lethal within four days; the results, however, were negative, since we were unable to appreciably prolong the lives of these animals or check the inevitable bacteremias.

A year previous Steinfield and I[65] had tried a large number of new mercurials including mercurophen but with negative results. I have also employed *mercurochrome* in dose of 0.005 mg. per kilo (approximately one-eighth of the maximal tolerated dose) in similar experiments, but with negative results although occasionally the lives of mice treated simultaneously with inoculation or within two hours thereafter were prolonged from one to three days beyond the controls. I have also used *arsphenamin* in dose of 0.02 gm. per kilo and *neoarsphenamin* in dose of 0.03 gm. per kilo, in similar tests with negative results.

It is to be admitted, however, that these experiments were severe tests for the curative activity of the compounds, although fashioned after the method for determining the curative activity of antipneumococcus serum. Recently Dr. Malcolm J. Harkins and I did over again some of the work, employing rabbits infected with repeated minute amounts of culture of virulent pneumococci lethal in about eight days. Treatment with mercurophen (0.005 gm. per kilo) and arsphenamin (0.03 gm. per kilo) by intravenous injection was without effect, the first dose of each drug being given four hours after inoculation followed by daily injections; mercurochrome occasionally prolonged the lives of some animals a few days, but all succumbed with pneumococcus bacteremia. I have not employed these compounds in the treatment of experimental pneumococcus pneumonia of rabbits or monkeys, but on the basis of these results I doubt if the arsenicals and mercurials employed in our tests would exert appreciable degrees of curative activity.

Mercurial Compounds in the Chemotherapy of Experimental Streptococcus Systemic Infections.—In 1920 and at various times since then, I have experimented extensively with mercurophen and other new organic compounds of mercury in the treatment of acute infections of rabbits produced with virulent strains of hemolytic streptococci, but with uniformly negative results. As a general rule, the untreated animals succumbed within five days after inoculation and almost unvariably with a severe bacteremia; the treated animals and especially those receiving intravenous injections of the compounds within two hours of the time of infection, sometimes lived a day or two longer, but none were saved although I am confident that the blood stream was frequently sterilized for brief periods following the injections of compounds.

In 1922, however, Piper,[66] reported experiments with rabbits infected with streptococci and treated with intravenous injections of mercurochrome in dose of 0.005 gm. per kilo, indicating that this compound had an appreciable bactericidal activity in the blood and in one instance, at least, apparently cured a severe local infection of an eye. On the basis of this word Piper began the treatment of puerperal sepsis with mercurochrome and with encouraging success, which I shall discuss in Chapter VIII.

Dr. Harkins and I have repeated Piper's experiments but not with very satisfactory results. I realize, however, that the strain of streptococcus employed by us may have been too highly virulent, since rabbits succumbed in thirty-six hours with extremely severe bacteremias. In some experiments

the dose of culture was so reduced that the animals lived for longer periods, but in some of these the untreated controls lived indefinitely and thereby rendered the result difficult of proper interpretation. But we did observe some effect upon bacteremias, although the sum total of experiments employing dozens of infected rabbits were disappointing insofar as complete cures were concerned.

We then turned our attention to experiments employing white rats, since the higher natural immunity of these animals for streptococci prevented the occurrence of overwhelmingly severe infections, but here again the results were largely of a negative character, although occasionally hopeful results were observed when the compound in dose of 0.005 gm. per kilo was given within an hour or two after inoculation and followed up by daily doses.

Better results, however, were observed with mice infected by subcutaneous injections of streptococci according to Morgenroth's method described in Chapter IV. As a general rule, we inoculated the mice every three days and produced thereby a streptococcus cellulitis with infection of the blood stream lasting from seven to ten days and more closely duplicating conditions as encountered among human subjects with streptococcus infections. Mercurochrome was given by intraperitoneal injection in dose of 0.005 gm. per kilo, at daily intervals and four hours after each inoculation. Controls receiving the drug alone lived indefinitely; untreated controls succumbed with severe streptococcus cellulitis and bacteremias, whereas 30 per cent., and sometimes more of the treated animals lived indefinitely and showed no local lesions at the site of inoculation. In my experience, this technic has proved the most satisfactory of all employed and I believe that mercurochrome demonstrated unmistakably some degree of curative activity. Curiously enough larger doses of mercurochrome up to 0.010 gm. per kilo, did not improve the results and indeed, animals treated with this amount sometimes died earlier than the untreated controls, which we ascribed to the toxic effects of the compound acting primarily as a depressor of resistance.

Salicylates and Related Substances in the Treatment of Experimental Streptococcus Arthritis of Rabbits; the Toxicity of the Salicylates.—One of the unsolved mysteries of therapeutics is the mechanism of the beneficial and even curative effects of the salicylates and related substances in acute rheumatic fever. Indeed, these effects are frequently so striking that many physicians have included the salicylates in this disease in the category of the specific chemotherapeutic remedies and I am, for this reason, including here a description of recent experiments bearing upon the antibacterial properties of these compounds *in vivo* for streptococci.

The etiology of acute rheumatic fever, however, has not yet been solved although the majority of investigators in this field regard the disease as a bacterial infection and probably due to some member of the streptococcus group (*Diplococcus rheumaticus*). The relation of this organism to the etiology of rheumatic fever has been thoroughly reviewed by Swift and Kinsella[67] and need not be here discussed; Miller[68] has also recently reviewed the subject and reported an extensive series of attempts to transmit the disease to rabbits and guinea-pigs by inoculation with whole blood, serum, joint fluid, pleural fluid, throat washings, and suspensions of tonsil tissue of patients, with negative results insofar as the joints were concerned, although myocardial lesions were apparently produced in one-half to two thirds of the animals. It must be admitted, therefore, that the etiology of acute rheumatic fever is as yet undetermined but on the other hand there can be no reasonable doubt of the occurrence of more chronic forms of arthritis due to streptococci and presumably as focal infections.

Therefore, the experiments reported by Davis,[69] Fantus, Simmonds, and Moore,[70] Swift and Boots[71] in the production of arthritis in rabbits with hemolytic and non-hemolytic streptococci and its treatment with salicyl compounds are of interest. After an extensive series of experiments they concluded that rabbits inoculated intravenously with non-hemolytic streptococci, while under the influence of full therapeutic doses of sodium salicylate, developed almost as many inflamed joints as the untreated controls similarly inoculated. The salicylated rabbits, on the other hand, had a much higher proportion of mildly inflamed joints than did the controls. This anti-inflammatory action was most evident in the animals inoculated with streptococci of the lowest virulence, and could not be demonstrated in animals inoculated with hemolytic streptococci.

Hanzlik and Karsner[72] have shown that sodium salicylate in doses of from 0.3 to 0.5 gm. per kilo of body weight in dogs and cats leads to severe cloudy swelling of the kidneys, and often to acute tubular nephritis. When we consider that from 0.15 to 0.2 gm. of salicyl per kilo of body weight is the maximum amount that can be tolerated for two or three days by most patients without developing severe albuminuria, it is probable that these animals used by Fantus and his co-workers had severe renal changes. On the other hand, sodium salicylate is of rather low toxicity for rats and rabbits, as I have observed these animals to withstand amounts as high as 0.3 to 0.4 gm. per kilo by single intravenous injection without apparent harm.

Mercurial and Arsenical Compounds in the Chemotherapy of Experimental Staphylococcus Infections.—As stated in Chapter IV, the only satisfactory method so far developed in my experience for producing generalized staphylococcus infections for chemotherapeutic experiments in the intravenous injection of rabbits or rats with sufficient amounts of culture of *Staphylococcus pyogenes aureus* to produce infection of the kidneys, heart, diaphragm and other internal organs and comparing the extent and degree of infection among treated animals with untreated controls. Numerous experiments of this kind employing mercurophen and other organic mercurials, arsphenamin and neoarsphenamin, have almost invariably produced negative results. Mercurochrome, however, in dose of 0.005 gm. per kilo has apparently cleared the blood stream of staphylococci in some animals and likewise sharply reduced the extent of abscess production in the internal organs, but the lesions are such that the results cannot be expressed in terms of percentage of survivals since the majority of animals do not succumb in a given period, as in experimental streptococcus and pneumococcus infections. I have had no evidence so far of mercurochrome, given by intravenous injection, sterilizing staphylococcus abscesses of the internal organs or of the skin following subcutaneous inoculation, but the drug has unmistakably sterilized the blood of experimental animals at least for brief periods of time and thereby prolonged the lives of some animals with less rapid loss of weight and other toxic effects.

Mercurial and Arsenical Compounds in the Chemotherapy of Experimental Systemic B. Coli Infections.—Since Young and his associates have found mercurochrome efficacious in the treatment of *B. coli* infections of human beings, Dr. Harkins and I have endeavored to study its effects in experimental *B. coli* infections of rabbits. A culture was employed, which upon intravenous injection, proved fatal for rabbits in approximately five days with bacteremia (positive blood cultures). Treatment with mercurochrome by intravenous injection in dose of 0.005 gm. per kilo, the first dose being given four hours after inoculation followed by several daily doses, prolonged the lives of some animals for eight days and in a few instances for indefinite periods.

We have not conducted a sufficient number of these tests, however, to warrant definite statements but believe that enough has been done to show that mercurochrome may favorably influence rather severe experimental *B. coli* infections. Similar experiments employing mercurophen in dose of 0.001 gm. per kilo and arsphenamin in dose of 0.01 gm. per kilo, yielded negative results.

Arsphenamin and Neoarsphenamin in the Chemotherapy of Experimental Swine Erysipelas Infections.—In 1917, Bierbaum[73] reported that both arsphenamin and neoarsphenamin were curative for mice inoculated with *B. erysipelatis suis* (*Erysipelothrix Rosenbach*) of swine erysipelas. Baum and Harrenheiser,[74] however, had previously reported that they were unable to confirm Bierbaum's claim that these arsenicals were bactericidal for this organism *in vitro* and that their *in vivo* tests likewise yielded negative results. Kolle and Schlossberger,[75] however, have recently repeated some of this work with dyes and various arsenicals and found that arsphenamin and neoarsphenamin as well as their metallic salts, were effective when used very early in the disease and in doses which approached the limit of toleration.

Chemistry of Mercurial, Creosote and Hexamethylamin Compounds in Relation to the Chemotherapy of Bacterial Diseases.—The chemistry of the compounds discussed in the preceding sections bears an important and fundamental relationship to this whole subject of selective bacteriostasis *in vitro* and disinfection *in vivo*, but unfortunately we do not possess at present much definite information on this question of chemical constitution in relation to chemical disinfection in bacterial diseases.

Insofar as the compounds of *mercury, copper, gold, silver and other heavy metals* are concerned, I believe that bactericidal activity both *in vitro* and *in vivo* is largely a matter of disassociation of the metallic ions. Pilcher and Sollmann[76] have expressed this view in relation to the organic protein and colloidal silver compounds and they have found that blood does not hinder the bactericidal properties of the ionized, inorganic silver salts quite as much as normal saline solution, but hinders the colloidal silver-protein compounds considerably more by acting as a protective colloid and thereby securing a finer suspension of silver chlorid facilitating its solutions or by combining with silver and thereby diminishing its ionization. I have discussed this subject of ionization, however, more fully in Chapter LIII in relation to the mechanism of the toxic effects of mercury for body cells and of curative activity in syphilis; I believe that the same principles apply to the organic and inorganic compounds of other metals. However, it cannot be stated that the toxicity and bactericidal properties of these compounds is solely one of dissociation or ionization of the metallic ions. Abelin,[77] for example, states that the toxic effects of the mercurials can be diminished by the introduction of a sulpho-or sulphamino-group or through double carbon connection of mercury. The relation of the sulpho-group is particularly interesting and important and probably possesses a relation to the toxicity of the organic arsenicals as well, as discussed in Chapter XLVI.

Schranth and Schoeller[78] have observed that the disinfectant powers of organic mercury compounds were increased by substitution of the less acid phenolic hydroxyl for the carboxyl. They also showed that, of the three *isomeric mercuriated* cresols, the meta-derivative is the most potent, while the ortho-hydroxy-mercuri-phenoxid is more effective than the para-compound, and also that the entrance of a second hydroxymercuric group increases bactericidal activity.

In a study of the tuberculocidal activity of a series of new organic preparations of mercury with various phenolic and anilin compounds, DeWitt[79] has also obtained some interesting data bearing upon the relation of chemical constitution to bactericidal activity. Bechhold and Ehrlich[80] and Bechhold[81] in a study of creosote compounds have emphasized the fact that the effect of a given chemical on one species of bacteria may not be duplicated with another species, and hence general laws covering the influence of various modifications of a substance on its bactericidal action cannot bededuced from limited observations. Thus it was found that the introduction of halogen atoms into phenols increases the disinfectant action somewhat in proportion to the number of added halogens.

But it is hardly profitable at present to review in this treatise the numerous opinions expressed from time to time on the relation of chemical constitution to disinfectant activity of the various compounds already listed or described in the present chapter, but another example of what persistent and good work has done in this important field may be found in the papers of Jacobs and his colleagues in their studies with the quartenary salts of hexamethylenetetramin.

Toxicity of the Mercurial Compounds in Relation to the Chemotherapy of Bacterial Diseases.—In regard to the treatment of bacterial diseases, only the mercurial compounds require much consideration from the standpoint of toxicity and especially mercurochrome, because it is the only compound of the kinds discussed in the chapter being generally employed in addition to the organic arsenicals like arsphenamin, neoarsphenamin and sodium cacodylate.

The toxicology and pharmacology of mercury and the arsenicals are, however, discussed with more detail in succeeding chapters and here I shall but briefly summarize the toxic doses of mercurophen and mercurochrome for the lower animals by intravenous injection and the effects produced in human beings by the intravenous injection of these compounds.

Toxicity of Mercurophen.—As a general rule, the maximum tolerated dose of *mercurophen* for white rats by intravenous injection is about 0.006 to 0.008 gm. per kilo of weight. The compound is, therefore, slightly less toxic than mercuric chlorid which has a maximum tolerated dose of about 0.002 to 0.004 gm. per kilo. I have injected mercurophen intravenously in adults in dose of 0.06 gm. or 12 to 15 c.c. of a 0.5-per cent., solution, corresponding approximately to one-eighth of the maximum tolerated dose without reactions; possibly larger doses would produce reactions similar to those produced by mercurochrome, but I have used the drug only in the treatment of syphilis as will be described in succeeding chapters, and general reactions have not been produced by doses of this size although the gingival tenderness and diarrhea of mercurialization have sometimes occurred.

I have already mentioned the toxicity of mercurophen by subthecal injection in the treatment of experimental meningitis. Special mention may be made, however, of the fact that solutions of this compound are particularly well borne by the skin and that individuals possessing a hypersensitiveness to bichlorid of mercury with the production of dermatitis have used it without such reactions. Dr. Schamberg, Dr. Raiziss and I have also observed that it is well borne by mucous membranes and may be employed in dilutions of 1:2000 to 1:4000 for the treatment of conjunctivitis and vaginitis although somewhat higher dilutions, like 1:5000 to 1:7000, should be used for irrigation of the male urethra to avoid burning and other symptoms of irritation.

Toxicity of Mercurochrome.—Mercurochrome is much less toxic due to its lower content of mercury and slower dissociation. White rats ordinarily

stand doses as high as 0.030 to 0.040 gm. per kilo without apparent harm although rabbits and dogs are more susceptible. Young, White and Swartz state that they have noticed a variation in the amount of the drug that rabbits and dogs could tolerate. Ten mg. per kilogram invariably killed rabbits in twenty-four hours, and no gross lesions were found at necropsy. Rabbits receiving 5 mg. per kilogram showed a decrease in phenolsulphonephthalein output and an albuminuria that lasted about a week. Dogs tolerated 10 mg. per kilogram very well with no evidence of discomfort or illness. In each instance there was produced an albuminuria without casts and a temporary reduction in phenolsulphonephthalein output but no rise in blood urea. The albuminuria persisted about five days. At no time were casts found. The phenolsulphonephthalein output returned to normal with the disappearance of the albuminuria. No evidence of kidney damage was found at necropsy on animals killed at the end of the experiments. With this toxic limit established no harm is to be expected from the small amount of the drug that may be absorbed when used locally in the genito-urinary tract.

One-per cent. solution mercurochrome-220 gave no evidence of irritating qualities when used in the conjunctival sac of rabbits. Solutions of this drug in strength from 0.1 to 5 per cent., have been used in the human genito-urinary tract as a local antiseptic. In the kidney pelvis a 1-per cent. solution was used. This was slowly injected through the ureteral catheter, the catheter was plugged, and the solution was retained for five minutes. There has been no sign of irritation or reaction following its use. This procedure has been carried out three times in one week in some instances. In the urethra, a 5-per cent. solution caused only temporary burning when retained five minutes, and a number of cases of acute urethritis have been treated by the use of 1-per cent. solution injected 4 times a day, the solution being retained five minutes at each injection. There has been no irritation beyond occasional temporary smarting.

Hill and Bidgood[82] have recently made a special study of the effects of mercurochrome on the kidneys of dogs reaching the conclusion that the intravenous injection of this compound "causes a mild reaction in the kidney which is directly proportional to the dose given. There is no actual destruction of tubular epithelium from doses as high as 7.5 mg. per kilo of body-weight, but with 10 mg. per kilo there is definite renal damage, so that it would be unwise to use so large a dose clinically."

Miss Rule and I, in our experiments upon the chemotherapy of experimetal pneumococcocus and streptococcus meningitis of dogs, rabbits, guinea-pigs and rats, have observed that the maximum tolerated dose of mercurochrome by subthecal injection is between 0.0001 and 0.0002 gm. per kilo. Injected intracisternally a dose of 0.0001 gm. per kilo is always well borne while a dose of 0.001 gm. frequently proves fatal in thirty-six hours. As a general rule, 0.0001 gm. per kilo can be injected daily for six or more doses, but 0.0002 gm. per kilo is generally fatal after about 3 or 4 daily injections.

Mercurochrome-220 soluble has been prepared for intravenous administration and is generally injected in dose of 0.005 gm. per kilo of weight dissolved in hot distilled water. The solution does not require heating, since it is rapidly self-sterilizing. This dose corresponds to about 0.3 gm. or 5 grains for an adult weighing 130 to 140 pounds and is generally administered in a 1-per cent. solution (25 to 30 c.c.) *slowly* injected. Smaller doses like 10 to 15 c.c. of a 1-per cent. solution, may produce practically no reaction at all beyond increased pulse rate and flushing, but the larger dose is almost sure to produce a severe diarrhea in one-half to six hours and the stools are likely to be red in color due to fluorescein sometimes mistaken for blood; the urine

will also be red in color. The patient may complain of nausea and vomiting, which also may be colored red. A rather severe chill is produced, lasting from ten minutes to an hour but usually not more than twenty minutes, and the temperature is increased by one to three degrees with increased pulse rate. As a general rule, these reactions subside in a few hours.

I have never seen nor heard of a fatal acute reaction of this kind but several individuals have succumbed to the later toxic effects of mercurochrome. I know of several fatalities due to acute nephritis with almost total suppression of urine. Mercurochrome should not be used promiscuously or too freely, and especially if nephritis is present, but I shall discuss this matter at more length in Chapter VIII devoted to the practical chemotherapeutic management of bacterial diseases.

Mechanism of the Curative Activity of the Heavy Metals in Bacterial Diseases.—Unfortunately, but very little has been determined regarding the mechanism of the antibacterial properties *in vivo* of the compounds of mercury, gold, silver, copper, arsenic, creosote, etc., discussed in this chapter. Whatever direct bactericidal effects they may have *in vivo* would appear to be due to the metallic ions after dissociation of the compounds and insofar as the mercurials are concerned, the subject is discussed at length in Chapter XXIV, dealing with their antispirochetal properties. Whether or not the mechanism of curative activity of the mercurials is the same in bacterial diseases as in syphilis cannot be stated; but it would appear that the ions of mercury have a combining affinity for *Sp. pallida* or in some other way are most toxic for these parasites.

It has been frequently suggested that the acute mercurochrome reaction and its curative effects in acute bacterial infections is due to a non-specific protein reaction ascribed to the effects of a new compound of mercury with the plasma proteins. It is true that the reaction bears some resemblance to the effects produced by the intravenous injection of vaccines, peptones and other foreign proteins, but the mercurochrome reaction in my opinion is a colloidal phenomenon and similar in its mechanism to the anaphylactoid reactions produced by the intravenous injection of variety of colloidal preparations of the heavy metals, arsenic, various proteins, etc. According to the results of my experiments with rabbits, the intravenous injection of 0.005 gm. of mercurochrome per kilo usually produces a definite total increase of the leukocytes, chiefly due to an absolute increase of the polymorphonuclear neutrophils and these changes usually occur with an hour after injection and persist for several hours reaching pre-injection proportions at the end of twenty-four hours. It is not improbable but that these leukocytic changes exert an antibacterial influence. Dr. Ling has studied for me the effects of this amount of mercurochrome upon the proteases of the plasma of rabbits, with the following results, expressed in terms of the number of milligrams of on-coagulable nitrogen per 100 c.c. of serum after forty-eight hours' digestion:

	Rabbit 1	Rabbit 2	Average
Before injection	4.2	1.4	2.8
4 hours after injection	2.8	1.4	1.1
24 hours after injection	1.4	0.7	1 0

It will be observed, therefore, that mercurochrome intravenously in rabbits causes a slight drop in the proteolytic power of the serum, so that it is probably not permissible to ascribe any material part of its antibacterial effects *in vivo* to a mobilization or increase of the serum proteases.

In truth we do not know how the colloidal reactions are produced or how bacteria in the blood are destroyed by the mercurials and other compounds mentioned in this chapter; these are still very obscure problems offering great difficulties in elucidation, but warranting and urgently demanding investigation for the purpose of placing the chemotherapy of the bacterial diseases upon a more scientific basis and removing it from the realm of its present state of almost pure empiricism.

Compounds of Mercury, Arsenic and Other Substances in the Chemotherapy of Bacterial Diseases of Man.—It will be apparent from the preceding review of the chemotherapy of bacterial diseases with compounds of mercury, gold, copper, silver, arsenic, creosote, etc., that the subject is still largely if not almost entirely, in the experimental stage. But enough has been done to show that some bacteria may be removed from the blood stream at least by some of these compounds, although there is much less evidence of curative activity in localized bacterial infections of the fixed tissues.

Practically the only compounds of this group used in the treatment of bacterial diseases of man are the arsphenamins in anthrax and streptococcus infections, creosote and guaiacol derivatives in tuberculosis and associated secondary infections, the salicylates in acute rheumatic fever, sodium cacodylate in streptococcus endocarditis and mercurochrome in acute streptococcus, staphylococcus and *B. coli* infections. Of course the colloidal silver-protein and various mercurial compounds have also been used in the treatment of localized infections by topical application and this is likewise a form of chemotherapy, but, aside from the examples just mentioned, we have as yet made but little advance in the chemotherapy of systemic infections of human beings with these compounds.

But encouraging results have been obtained and I firmly believe that the whole field of the chemotherapy of bacterial diseases offers much hope for success and no one will deny the importance of continuing investigation in so important a field and especially since the specific treatment of acute and chronic bacterial diseases by biological substances as serums, vaccines and similar agents so frequently fail to produce beneficial results. But the present state of the value of these compounds in the treatment of bacterial diseases of man is a large subject and I shall discuss in the succeeding chapter what chemotherapy has to offer.

CHAPTER VIII

CHEMOTHERAPY OF BACTERIAL DISEASES OF MAN AND THE LOWER ANIMALS

In this chapter it is my purpose to summarize briefly what may be designated as the practical applications of chemotherapy in the bacterial diseases. The subject, however, is still in the infancy of its development and while some progress has been made, we do not possess as yet chemical agents for the disinfection of the body of bacteria comparable in efficiency to arsphenamin and its congeners for the treatment of syphilis, quinin for malaria and other remedies like tartar emetic, ipecac, etc., for various protozoan and metazoan diseases. But chemotherapeutic research has resulted in placing at our disposal additional remedies for combating infection, not as substitutes for our usual methods, but rather as adjuvants or aids capable, when properly employed, of improving the treatment of a number of bacterial diseases. I have already discussed in Chapter III some of the more important principles concerned and it is particularly important to bear in mind the influence of the pathological tissue changes of the various acute and chronic infections, the importance of surgical drainage and the advisability in some diseases of combining serum and other forms of biologic therapy with chemotherapy in order to obtain the best results.

Chemotherapy of Wounds, Sinuses and Ulcers.—The treatment of infected wounds with antiseptics has long held a place of great interest in surgical practice. Before the discoveries of Lister one is impressed with the frequency with which wines and balsamics were incorporated into various mixtures for application to wounds, and the good effects were probably due to the antiseptic properties of alcohol. With the work of Lister and the discovery of the pyogenic bacteria, interest in this subject was greatly renewed, although attempts to disinfect wounds were frequently defeated by the use of too toxic and too irritating chemical substances lacking in penetrability and subject to sharp reduction in bactericidal activity by contact with the proteins and the salts of the polybasic acids of necrotic muscles, etc. But the idea of preventing infection or affording aid in the recovery from infections of wounds by the application of disinfectants, has never been entirely abandoned and during the World War interest in the subject was greatly renewed and especially by the work of Carrel and Dakin and their associates with antiseptics of the chlorin group.

It is not usually a difficult matter to determine by bacteriological examinations the kind or kinds of bacteria responsible for suppuration in a wound, although special methods are required for the anaërobes. As a general rule, both Gram-positive and Gram-negative organisms are present in chronic infections and the former are nearly always more numerous and important than the latter, since the Gram-positives include such common aërobes as the streptococci, staphylococci and diphtheroid bacilli, as well as the anaërobes like *B. tetanus*, *B. edematis maligni* and other spore bearing organisms of this group so important in wounds contaminated with dirt. The Gram-negatives are usually *B. coli*, *B. pyocyaneus* and *B. proteus* of much lesser importance. But in the chemotherapy of wounds and sinuses, due consideration must be given to both groups and preference given to a disinfectant or combination of disinfectants known to possess a sufficiently high bactericidal and bacteriostatic activity for spore bearing and non-spore bearing. Gram-positive and Gram-negative, aërobic and anaërobic organisms.

As is well known, wounds do not usually show bacteria in either smears or cultures for at least four to twelve hours and in fresh wounds the surgeon must exercise his judgment on the question of probable bacterial contamination according to the nature and location of the injury; but where it is at all likely that infection is present, disinfection should constitute a very important part of treatment and a subject worthy of close attention from the standpoint of selection of disinfectant and the manner of its application.

Naturally enough, a rather large group of substances and a variety of methods for application have been advocated and indeed, there is by no means a uniformity of either opinion or practice among surgeons upon these questions. It would appear, however, that the choice of antiseptic and the method of its application should be influenced by the conditions and circumstances surrounding individual cases and that no one antiseptic or method is applicable to all wounds. As repeatedly stated, the antiseptic treatment of fresh and suppurating wounds can never be a substitute for drainage and well-established surgical principles in general, but I believe that its possibilities have been generally under estimated as an adjuvant to these. The subject is indeed a very large and comprehensive one, but I shall attempt to summarize briefly here in a practical manner the purely antiseptic or chemotherapeutic phases, without touching upon the surgical and technical aspects so well covered by Carrel and Dehelby[1] and standard works on surgery in general.

1. In small *fresh wounds* which do not require irrigation, the instillation of a 2-per cent. solution of dichloramin-T (sodium toluene sulphondichloramin) in sterile paraffin oil may prove effectual in preventing suppuration and constitutes an excellent first dressing. Thorough cleansing and instillation with a 1:500 solution of mercurochrome in water is likewise recommended. In some cases a paste is to be preferred for furnishing an antiseptic over a longer period of time and I have advised the following 1:500 paste of mercurochrome during the past few years because of its high bactericidal activity, penetrability and soothing blandness: mercurochrome 0.4 gm.; sterile almond or paraffin oil 100 c.c. and bismuth subgallate, 100 gms.

In large fresh wounds which will probably suppurate, and especially those involving bones and joints, it would appear advisable to provide at once for irrigation with Dakin's 0.5-per cent. solution of neutral sodium hypochlorite solution or a 1- to 2-per cent. solution of chloramin-T (sodium toluene sulphonchloramid). Even though the wound may not be sufficiently extensive to demand a series of Carrel tubes, irrigation at two to three hour intervals through a single tube may suffice if the solution is brought into contact with all parts of the wound. Acriflavin gauze may be employed as an antiseptic dressing and particularly since it is odorless, non toxic, does not inhibit phagocytosis or otherwise injure the tissues. It is true that it stains the linen, hands, etc., but these stains are removable by any good soap or by cotton dipped in acid alcohol (3 per cent. hydrochloric acid in alcohol); the formation of the yellow pellicle on the surface of the wound in six to seven days may be sometimes overcome by using normal or hypertonic saline solution.

2. As so clearly demonstrated by Carrel and his colleagues, it is possible to disinfect *suppurating wounds* if provision is made for bringing a properly selected disinfectant into frequent and intimate contact with the tissues. The working out of a method by Carrel whereby this may be accomplished constitutes, in my opinion, one of the triumphs of modern surgery and, even though there may be a difference of opinion on the question of whether sterilization may be carried to the point where it is safe to sew up some

wounds, yet there can be no difference of opinion on the advisability of preventing, limiting or stopping suppuration by disinfectants which do not hinder the processes of healing or add to the dangers of secondary hemorrhage. Insofar as the disinfectant is concerned, one may employ Dakin's solution provided the reaction is properly adjusted to guard against vascular ulceration by free alkali; a 1-per cent. solution of chloramin-T exerts more prolonged antiseptic action, is less toxic and irritating and is to be preferred when acting in the presence of much blood. Or what is better still is to use Dakin's solution for the first day or two followed by the latter. I have also added mercurochrome* to both of these solutions in the proportion of 1 gram to 2000 c.c. to increase bactericidal activity when it was desired to bring about as quick sterilization as possible and especially in streptococcus, gas and malignant edema infections; this gives a 1:2000 solution, but occasional irrigations are not at all dangerous from the standpoint of absorption of toxic amounts of mercury even in large wounds.

Churchman[2] has advocated a mixture of 1 gram each of gentian-violet and neutral acriflavin in 2000 c.c. of sterile distilled water. The former is for the destruction of Gram-positive and the latter for Gram-negative organisms. The solution is of a deep plum color and is objectionable from the standpoint of staining the dressings and bedclothes unless considerable care is exercised, but it is absolutely non-toxic and possesses a high degree of bacteriostatic and bactericidal activity in the presence of pus. Of course, mixtures of these dyes with Dakin's solution cannot be used because of immediate precipitation; neither can they be mixed with mercurochrome for the same reason, but the dyes alone are highly bactericidal and may be used as a substitute for the chlorin compounds for irrigation purposes.

3. Mention may be made of the disinfection of that large group of infected wounds and *sinuses* following operations upon infected tissues requiring drainage. Needless to state, the presence of a suture, necrotic bone or other foreign body acting as the focus of continued suppuration requires surgical removal, but what may be done by appropriate chemotherapeutic measures in the removal of the secondary infection which may be long continued and persistent if the general and local resistance of the patient is greatly reduced? In these I believe that much can be done as an adjuvant to surgery by disinfection and autogenous vaccine therapy. The indications are to use antiseptics in such form that their activity will be maintained over a long period of time in order to reduce to a minimum the degree of handling in order not to disturb granulation and healing. The disinfectant must also be one least likely to prove toxic for fibroblasts and it should not retard phagocytosis or neutralize other immunological processes. For this purpose a 2-per cent. solution of dichloramin-T in sterile paraffin or almond oil may be employed and I have also used the paste of mercurochrome described above; also the following mixture which is thin enough to be poured into a wound or injected into a sinus for the purpose of reaching all parts:

Gentian-violet Neutral acriflavin	.aa	0.5 gm. (gr. viiss)
Bismuth subgallate		300.0 gm. (℥ ixss)
Almond oil		300.0 c.c. (f℥ x)

This gives approximately a 1:1200 suspension of the two bactericides suitable for the treatment of wounds caused by either Gram-positive or Gram-negative organisms or a mixture of the two, as is so commonly found

* Throughout I am using the word "mercurochrome" as a synonym for "mercurochrome-220 soluble." The latter is the sodium salt of mercurochrome but the free acid is not employed and I believe the shorter term is just as good.

in smears and cultures. The paste is not thick enough to retard drainage, the tissues are gradually stained by the dyes and the more deeply situated organisms are thereby reached and gradually destroyed.

4. Finally the matter of the disinfection of *ulcers* may properly command our attention. Needless to state, syphilitic ulcers respond promptly to appropriate systemic treatment and the local lesions so frequently caused by the breaking down of gummas do not require any special consideration. But the ulcers of the aged due primarily to vascular sclerosis plus bacterial infection, as well as the ulcers of diabetes, tuberculosis, and even of epithelioma, may require something in the way of local disinfection for the purpose of checking tissue necrosis as much as possible while other appropriate therapeutic measures are being employed. As a general rule, bacteriological examinations show the presence of staphylococci, *B. pyocyaneus*, *B. coli*, *B. proteus* and diphtheroid bacilli but pathogenic anaërobes are generally absent. A great number of various local applications have been advocated for the primary purposes of disinfecting the tissues and stimulating the processes of repair. Most, however, are lacking in penetrability and fail to reach the organisms situated in the granulation tissue and deeper recesses of the lesions. As a general rule, only such preparations are to be preferred in order that disinfectant activity may be prolonged and granulations protected, but these should not interfere with drainage and I believe that any of the following are to be recommended: (1) a 1-per cent. solution of dichloramin T-in oil; (2) a 1:2000 of mercurochrome in equal parts of almond oil and bismuth subgallate; (3) A 1:2000 of acriflavin and gentian-violet in equal parts of almond oil and bismuth. The two last mentioned readily stain and penetrate the tissues and all three are highly bactericidal in the presence of the excretions without being injurious to the granulation tissue or irritating to the tissues.

Chemotherapy of Burns.—From the standpoint of the chemotherapy of burns the chief indication is to reduce infection and scarring to a minimum. At the same time local applications should be anesthetic, like packs of ½ to 1 per cent. novacain, with 10 minims of adrenalin in each ounce, at least for the first day or two, and always bland in order to protect granulation and healing. As a general rule, the surgical removal of devitalized tissue may be deferred for twenty-four to forty-eight-hours for recovery from shock at which time this and the puncturing of vesicles may require attention followed by spraying with 2-per cent. solution of dichloramin-T every three hours.

Many different disinfectant preparations have been advocated, like 1-per cent. solution of picric acid, which is about 5 times more bactericidal than phenol. The well-known carron oil (equal parts of linseed oil and lime water) is soothing and feebly bacteriostatic as a result of its alkalinity. The disinfectant should be especially active for staphylococci and streptococci, particularly the former, and 1:1000 gentian-violet or acriflavin serves this purpose very well, as in the following paste:

Gentian-violet or acriflavin	0.1 gm. (gr. iss)
Bismuth subgallate	50.0 gm. (℥iss)
Almond or paraffin oil	50.00 c.c. (f℥iss)

The addition of 0.5 gm. of butyn renders the paste anesthetic and its application affords prompt relief, which may be required for the first dressing. Mercurochrome in the same dose may be substituted for the dye in the above formula, and owing to its low toxicity there is not usually danger from absorption, except in very extensive applications.

If the burned area is sprayed or painted with one of the paraffin mixtures, it may be well to incorporate a bactericide in order to prevent staphylococcus suppuration of the granulation as much as possible. For this purpose,

however, our choice of disinfectant is quite limited since gentian-violet, acriflavin, mercurochrome, etc., are not soluble in these mixtures. Resorcinol, betanaphthol, oil of eucalyptus, etc., have been incorporated, but their bacteriostatic and bactericidal activities are very slight and I have found dichloramin-T to be much more active. A 2-per cent. mixture is made as follows:

Paraffin (melting point about 56°C.)	67 gm. (℥ij)
White Vaselin	25 gm. (℥vi)
Olive oil	6 c.c. (f℥iss)
Melt by minimum heating and add:	
Dichloramin-T	2 gm. (gr. xxx)

This mixture is highly bactericidal and has a melting point of about 50°C.; when used it should be melted at this minimum temperature and applied to the carefully dried burned area with a soft camel's hair brush or sprayed on with an atomizer, the electrically heated atomizer being especially useful. Bactericidal tests have shown that heating the mixture tends to slightly reduce its activity, probably by driving off a portion of the chlorin, and for this reason only sufficient for one application should be heated at a time as required.

Chemotherapy of Streptococcus Cellulitis, Lymphadenitis, Septicemia and Other Surgical Infections.—The chemotherapy of streptoccocus cellulitis and lymphangitis resolves itself into two phases, namely, disinfection of the local lesions and disinfection of the blood, if septicemia (bacteremia) develops.

Insofar as local measures are concerned, the establishment of adequate drainage of pus with least manipulation of the parts, elevation, and rest are of paramount importance; needless to state, external vigilance is required for the detection of new areas of pus formation requiring drainage, although the incision of merely inflamed tissues and especially glands may not be required. A large number of local antiseptics have been used, but I agree with Ochsner[3] that one of the best for cellulitis is a *saturated* water solution of boric acid; this should be applied hot in large wet dressings and kept warm by electric pads or hot water bottles. As stated by Ochsner, the addition of 95-per cent. alcohol to the boric acid solution in quantities of from 15 to 30 per cent. will add a dehydrating effect and help to make the limbs warm and comfortable, relieving the cold, clammy feeling of which the patient sometimes complains when watery boric acid solution alone is employed. I have also added to the boric acid solution or to the boric acid-alcohol solution, 1 gram of mercurochrome to the liter, which yields a 1:1000 solution of increased bactericidal activity. These solutions do not retard phagocytosis, but appear to aid leukocytic migration and the walling off of infected tissues; they frequently relieve the superficial lymphangitis and afford relief from the persistent pain, which not infrequently is excruciating in character.

If drainage tubes have been introduced, it is well to provide for irrigation at two hour intervals, using a syringe with very gentle pressure, or the Carrel method. I believe that neutral sodium hypochlorite solution (Dakin's solution) or 2-per cent. chloramin-T are best suited for this purpose, although the dressings should be changed frequently enough to keep the boric acid solution in contact with the skin as much as possible.

A blood culture should be made in all cases, as septicemia may be present even in those with relatively mild local lesions. If the blood is found sterile and the local lesions are regressing, nothing further is usually indicated or required. But if the local lesions are progressing, more energetic measures may be required and especially if the blood culture shows the presence of a streptococcus.

My first step in systemic therapy is to give 100 c.c. of polyvalent anti-streptococcus serum by intravenous injection with the usual precautions against anaphylactic shock. Since the infusion of physiological saline solution alone is sometimes efficacious for combating the toxemia, I frequently dilute the serum with 200 or 300 c.c. of saline solution and administer it with the usual arsphenamin apparatus. In severe cases a second dose of equal size is given twelve to twenty-four hours later. Even though the blood culture is sterile the administration of the serum is frequently indicated when the local infection is spreading, in order to combat the toxinemia, to prevent bacteremia and to aid in the walling off of the local lesions. I am convinced that virulent streptococci produce aggressin-like toxins capable of retarding phagocytosis; this toxin has long been known as a leukocidin or a poison capable of killing leukocytes, and one effect of the serum may be to neutralize it and to this extent favor leukocytic migration into the lesion and encourage phagocytosis. After one or two intravenous injections have been given, it is sometimes useful to administer subsequent doses of 25 to 50 c.c. by intra-muscular injection while mercurochrome, gentian-violet or some other chemical disinfectant is being administered at intervals by intravenous injection.

If, however, the local lesions continue to spread and especially if bacteremia (septicemia) develops, as indicated by positive blood cultures, more energetic measures will be required. It is good practice, therefore, to conduct a blood culture every day or, at least, every other day, during the acute spreading stages in order to detect and combat this bacteremia as early as possible. Even if the blood remains sterile, but the lymphangitis and suppuration continue to spread despite local and serum treatment, the intravenous injection of a disinfectant may be required.

For this purpose, mercurochrome, gentian-violet, neutral acriflavin, rivanol and arsphenamin have been employed. In my experience, mercurochrome has given best results, the dose being 0.005 gm. per kilogram of weight or about 23 c.c. of a 1-per cent. solution per 100 pounds. The solution is prepared in distilled water, but need not be sterilized, since in this strength it is rapidly self sterilizing. As reported by Young and Hill,[4] mercurochrome has apparently saved some desperately infected individuals and I have had three cases of streptococcus cellulitis and bacteremia whom I believe were saved by this drug administered by slow intravenous injection in the dose mentioned. Sometimes it is necessary to repeat the injection in three or four days and in one of my cases a dose was administered every two days for three doses in succession without apparent injury to the kidneys and with a successful outcome.

Young and Hill have also employed intravenous injections of gentian-violet with some success, although this compound, as well as neutral acriflavin, have been disappointing, in my experience, in cases of acute surgical streptococcus infections. Gentian-violet, however, is less toxic than mercurochrome and reactions usually do not occur at all. The dose is likewise 0.005 gm. per kilogram which corresponds to about 46 c.c. of a 0.5-per cent. solution per 100 pounds. The solution may be prepared in distilled water and does not require sterilization. It is quite safe to repeat the injections daily or every other day for several doses in succession. Shallenberger[5] has reported good results with this dye.

Browning and Cohen[6] and others have advocated intravenous injections of neutral acriflavin in about the same dose as gentian-violet, but Meleney and Zau[7] were quite unsuccessful with the drug in experimental streptococcus injections with rabbits and, as stated above, mercurochrome has proved

more efficacious in my experience. Rivanol, an acridin derivative developed by Morgenroth and his associates, has been recommended in dose of 30 to 50 c.c. of a 1:1000 solution by intravenous injection at daily intervals along with intramuscular injections of 50 c.c. of antistreptococcus serum; I have had no experience with this compound.

Arsphenamin and neoarsphenamin by intravenous injection have also been advocated and especially in streptococcus infections by Birt[8] and others; indeed, quite a large literature has accumulated upon their use in puerperal sepsis and other streptococcus infections, but in my experience they have been less efficacious than either mercurochrome or gentian-violet. If mercurochrome or the dyes are not administered it is always advisable to try the intravenous injection of neoarsphenamin in dose of 0.6 gm. for adults.

The value of blood transfusion is not to be under estimated and especially in prolonged cases with marked anemia, emaciation and other evidences of profound intoxication. If time permits, it may be helpful to immunize a compatible donor by administering subcutaneously 1000 million of the patient's streptococci in a vaccine daily for three doses, transfusion being done five to seven days after the last dose. But to be efficacious a large amount of blood is required. I have had cases, showing no perceptible benefit from 200 to 300 c.c. of blood, show a marked and prompt change in condition following 800 to 1000 c.c. and preferably by a direct method to minimize the degree of post-transfusion reaction.

Whether or not mercurochrome and the dyes administered by intravenous injection are able actually to penetrate the local lesions and disinfect the tissues is not definitely known; from the experiments of Hirschfelder, Malmgren and Creavy[9] this would appear unlikely from the doses mentioned, but yet clinically I have seen the local cellulitis and lymphadenitis apparently relieved in a manner suggestive of some direct local disinfection; however, the evidence of possible disinfection of the blood stream is quite definite and I regard the introduction of mercurochrome and the dyes into the therapy of streptococcus infections as a distinct advance and especially when employed with judiciously selected and administered biological forms of therapy.

Chemotherapy of Staphylococcus Cellulitis, Lymphadenitis, Septicemia and Other Surgical Infections.—While severe staphylococcus infections and especially septicemia (bacteremia) are rarer than streptococcus infections, yet they are more dangerous and especially since our biological forms of therapy are much less efficacious. For these reasons the chemotherapy of staphylococcus infections, and especially of septicemia, commands a great deal of interest and importance.

Local measures providing adequate drainage of pus, rest, elevation, etc., are usually sufficient. As a general rule, the washing out of abscess cavities is neither indicated nor required, although in some cases it would appear advisable when drainage is not as complete as it should be with consequent accumulation of pus, organisms and toxins. For this purpose 1:2000 mercurochrome may be recommended, as likewise 1:2000 acriflavin or gentian-violet. Rivanol in 1:1000 solution has also been employed with apparent success and Rosenstein,[10] Hartel and Kishaling[11] and others have advised its use in washing out abscesses or for direct injection into infected tissues. I have had no experience with it but abscesses do not ordinarily require chemical cleansing if good drainage is provided, and injections of this substance are stated to be quite painful and demanding local anesthesia.

Whenever tubes have been introduced for drainage, occasionally flushing may be indicated and for this purpose plain Dakin's solution or a 2-per cent.

solution of chloramin-T may be used because of their bactericidal activity and dissolving effect upon pus. I sometimes add 0.5 gram of mercurochrome to each liter of either of these solutions, since the resulting 1:2000 solution materially increases bactericidal activity without danger of absorption of toxic amounts of mercury. Local applications of saturated solutions of boric acid are not as efficacious as in streptococcus infections, but yet I believe they constitute one of the best applications available and especially a mixture of 700 c.c. of saturated watery solution of boric acid, 300 c.c. of 95-per cent. alcohol and 0.5 gm. of mercurochrome applied hot and kept hot with an electric pad or water bottles.

If these measures prove insufficient and the lesions spread, more energetic treatment is required. Blood cultures should be made, but with unusual care in the preparation of the skin so that if staphylococci are found and especially *Staphylococcus albus*, there need be no hesitation in concluding that an actual bacteremia is present rather than a culture contaminated by staphylococci from the skin. Eternal vigilance is required for the detection of new abscesses and especially in infections of the mammary glands. Anti-staphylococcus serum is hardly worth while. Young and Hill have reported some remarkable recoveries following the intravenous injection of mercurochrome in dose of approximately 23 c.c. of a 1-per cent. solution per 100 pounds of weight; in a series of five of my cases I believe it proved efficacious in two but was apparently unable to control the blood infection in the other three. The injections may be repeated every two or three days.

Gentian-violet and acriflavin have also been injected intravenously in dose of 0.003 to 0.005 gm. per kilogram of weight in 0.5-per cent. solution; Smith and Casperis[12] have recorded the recovery of a child of fifteen months, suffering with severe staphylococcus infection, ascribed to intravenous injections of gentian-violet and Shallenberger has also used it with apparent success in phlebitis and other staphylococcus infections. In my experience, however, neither gentian-violet nor neutral acriflavin in dose of 0.005 gm. per kilogram have succeeded in materially influencing the blood and tissue infections of three cases, one being due to *Staphylococcus pyogenes albus;* I believe mercurochrome is more likely to produce results and especially disinfection of the blood, although re-infection of the blood may occur, which, in one of my cases, was apparently prevented by the injection of 10 c.c. of 1-per cent. mercurochrome every two days over a period of a week. As in streptococcus infections, I believe that transfusion of 500 to 800 c.c. of blood is sometimes indicated and especially in long standing infections with recurrent abscesses and progressive anemia with emaciation. I am convinced that this procedure has turned the tide to a favorable outcome in two of my cases; infusions of physiological saline solution are also beneficial and much more so in my experience than the administration of saline by rectum by high enema or the drip method.

These measures may not prevent the development of abscesses and as long as the temperature and other symptoms indicate continued infection, a very careful watch should be made for their development. But the employment of mercurochrome, and possibly even of gentian-violet or acriflavin, may materially aid in preventing infection of the blood and even for disinfecting the blood, which thereby reduces the danger of metastatic abscesses in the kidneys and other organs, where surgical drainage cannot be instituted.

Special mention may be made of the value of intravenous injections of mercurochrome in *osteomyelitis* and especially staphylococcus infections. Splendid results are sometimes secured when these are given along with one or more blood transfusions and appropriate local treatment.

Various colloidal preparations of the heavy metals have also been used by intravenous injection in the treatment of staphylococcus infections. Silver compounds have commanded special attention and numerous preparations like "argochrome" (a silver compound of methylene-blue) and "argoflavin" (a silver compound of acriflavin) have been used by Leschke[13] and others on the basis that the rather sharp reactions are of the nature of "protein shock" reactions and beneficial to the patient.

Frouin[14] and others have also administered the salts of tin by mouth in the treatment of staphylococcus infections and the oxid in dose of 0.5 to 1 gm. per day is regarded as curative. My clinical experience with tin oxid, however, has not been satisfactory and bactericidal tests *in vitro* with "stannoxyl," stannous and stannic chlorids, stannic iodid, etc., have shown that they possess but slight bactericidal activity for staphylococci.

Chemotherapy of Puerperal Sepsis.—Puerperal sepsis is usually an infection of the puerperal uterus with streptococci of the hemolytic or non-hemolytic varieties and occasionally with staphylococci, by direct continuity and the lymph channels; the infection rapidly spreads locally and the blood stream becomes infected (septicemia) in the majority of cases, as shown by the results of repeated blood cultures. Obstetricians recognized a *puerperal sapremia*, ascribed to the absorption of the toxins of putrefactive bacteria and purely a local affair which disappears almost immediately upon the institution of drainage; but *puerperal sepsis* designates that extremely dangerous infection of the uterus with streptococci or staphylococci rapidly followed by infection of the blood and so frequently fatal that prompt and intensive treatment is required.

From the standpoint of chemotherapy, the disease resolves itself into attempts to disinfect the endometrium and the blood. I shall not enter upon a discussion of the much mooted subject of the intra-uterine douche, but I am convinced that the establishment of free drainage, the removal of organisms and toxins and the destruction of those that may be reached in the tissues by appropriate douching, are principles of primary importance in this as in other pyogenic infections. While antistreptococcus serum, mercurochrome and gentian-violet or acriflavin by intravenous injection may effectually check and finally remove the bacteremia, yet these compounds are without marked effect upon the local infection of the uterus and adnexa; furthermore, the blood may be continuously infected by the access of organisms from these local lesions and for these reasons I believe that appropriate local disinfection should be a part of the treatment of this dreaded and dreadful disease.

The return flow intra-uterine douche tube is well suited for flushing the uterus at intervals and harm cannot be ascribed to its use when it is properly employed with practically no force in order to guard against an extension of infection by pressure and mechanical injury. But as in the treatment of infected wounds elsewhere, best results follow repeated flushings at intervals of two or three hours and, I believe, that provision should be made for bringing a disinfectant solution into intimate contact with all portions of the uterine cavity and especially the head and horns, by means of the douche tube or even with perforated rubber tubes fashioned after the Carrel tubes, held in place by loosely applied packing and connected with a douche tank or bag. The *vaginal* canal may be likewise loosely packed with gauze impregnated with acriflavin and large vulvar pads provided for the collection of drainage of exudates and the returned disinfectant solution. Objections have been raised against this method on the basis that drainage may be impeded with consequent extension of the infection in the lymphatic and vas-

cular channels, but loose packings which may be renewed once a day cannot be regarded as responsible for these effects. Indeed, a distinct advantage may accrue from loose uterine and vaginal packings by reason of retaining a portion of the disinfectant solution and thereby prolonging its action. Furthermore, vaginal packing facilitates drainage and it should not be forgotten that the vaginal canal itself requires cleansing and disinfection since organisms and toxins from the uterine cavity may undergo absorption from the vagina unless these are removed or destroyed at frequent intervals.

Due care, however, must be exercised in the choice of disinfectant and, out of the large number that have been proposed, I believe that properly prepared neutral Dakin's solution or a 1-per cent. solution of chloramin-T is to be preferred. They are non-toxic, bactericidal, are not ordinarily irritating or painful and tend to dissolve the exudates, which thereby facilitates drainage. Every two or three hours a pint or more may be gently passed through the uterus and vagina, followed by a renewal of the vulvar pads, and twice a day the irrigation may be with a 1:4000 solution of mercurochrome prepared by dissolving 0.5 gram in 2000 c.c. of either the Dakin's or chloramin-T solution. Even though a portion of this solution is retained, and it is hoped that this occurs, there is no danger of the absorption of toxic amounts of mercury, and the bactericidal effects are enhanced with some staining of the endometrium which is likewise desirable as indicating penetration of the disinfectants. Gentian-violet, acriflavin or a mixture of the two in 1:2000 strength may be likewise used, but the above mentioned solutions have been more satisfactory; rivanol in 1:1000 solution has been employed abroad, but I have had no experience with it.

When localization occurs, drainage is required as in any other surgical infection. If in Douglas' pouch, this may be by vaginal puncture; but where there is a definite cornual abscess, infection of the upper portion of the broad ligaments, tubes, ovaries, etc., abdominal drainage may be required and in some cases it is well to provide for the irrigation of such lesions when extension of the infection is to be feared.

A host of substances have been advocated for the treatment of the septicemia by intravenous injection among which may be mentioned mercuric chlorid, formalin, colloidal silver, phenoiodine, arsphenamin, acriflavin, gentian-violet and mercurochrome. Of these, only arsphenamin, the dyes and mercurochrome are worthy of special mention.

Arsphenamin and neoarsphenamin have been used rather extensively and according to some reports with rather brilliant results as reported by Behan,[15] Miller and Chalfont[16] and others. The former in dose of 0.4 gm. and the latter in dose of 0.6 gm., may be tried, but I have not observed any pronounced bactericidal effects and doubt if one is justified in relying upon these products if one or two doses at daily intervals have failed to disinfect the blood as judged by symptomatic improvement and sterile cultures. Kiehne[17] has recently employed a mixture of 0.3 gm. of neoarsphenamin dissolved in 5 or 6 c.c. of water to which is added 2 c.c. of 1:100 mercuric chlorid; this greenish-black mixture is injected intravenously every two or three days and is employed abroad by Linsser in the treatment of syphilis. He has given as many as five injections and believes the results justify employing the method. Piper[18] has introduced the method of treatment with intravenous injections of mercurochrome and with some success; Whitehouse[19] has advocated the intravenous injection of neutral acriflavin in dose of 10 to 15 c.c. of 1:1000 solution morning and evening. Aron[20] has employed intravenous injections of "fulmargin," stated to be a colloidal silver preparation produced by electrical dispersion of the metal and with no protective protein;

Loeser[21] has injected "vuzin" (iso-ethylhydrocuprein) intravenously and for uterine douching, etc.

Antistreptococcus serum has been employed for many years and with occasional brilliant results; I believe that it should always be employed along with chemical disinfectants. Frequent transfusions of small amounts of blood has been advocated by Polak, but I have never observed these to have an appreciable influence upon the septicemia, although in prolonged infections with progressive anemia and emaciation, I believe that the transfusion of 600 to 800 c.c. of blood, preferably by a direct method, has been a life saving measure.

I have seen best results in the treatment of the septicemia by a combination form of treatment with antistreptococcus serum, mercurochrome, the dyes and blood transfusion after the following plan:

1. The *early* intravenous injection of 100 c.c. of polyvalent antistreptococcus serum diluted with 200 c.c. of saline solution and with the usual precautions for the prevention of anaphylactic shock. This dose is sometimes repeated in twelve to eighteen hours and thereafter 50 c.c. is given intramuscularly every other day for three or four more doses, either alone or in association with intravenous injections of mercurochrome or one of the dyes.

2. If a prompt therapeutic result is not obtained with the two doses within forty-eight hours, mercurochrome is injected intravenously in dose of 0.005 gm. per kilogram, which corresponds to 23 c.c. of a 1-per cent. solution per 100 pounds of weight. The injection is given very slowly and since the patient usually needs saline solution, I sometimes dilute this dose with 200 to 300 c.c. of saline and infuse it with an arsphenamin outfit.

3. A blood culture is made twenty-four hours later and, if positive, a second injection of mercurochrome is given (about 3 days after the first). If, however, examination of the urine indicates the presence of kidney irritation, I administer either gentian-violet or neutral acriflavin in dose of 40 c.c. of a 0.05-per cent. solution diluted in some instances with 100 to 200 c.c. of saline solution. Or these dyes may be substituted for by the intravenous injection of 0.4 gm. of arsphenamin (disodium salt) or 0.6 gm. of neoarsphenamin administered in the usual manner. As a general rule, however, mercurochrome can be safely given every three days for three or four doses and is the drug of choice, the injection being stopped with symptomatic improvement and sterile blood cultures.

4. At the end of a week or ten days some patients are benefited by blood transfusion and in my experience best results follow the infusion of 500 to 800 c.c.

5. At the same time, local disinfection is to be instituted as early as possible, according to the plan given above and the usual additional measures of diet, plenty of alcohol, glucose or saline solutions by rectum, etc., should not be overlooked.

Chemotherapy of Bacterial Endocarditis.—Unfortunately, chemotherapy has but little or nothing of proven and definite value to offer at present in the treatment of bacterial endocarditis, so apt to be predisposed by defects to infection usually caused by *Streptococcus viridans* and less commonly by the pneumococcus, gonococcus, staphylococci and *B. influenzæ*. The disease has a high mortality, although when caused by streptococci of low virulence, recovery may ensue, as indicated by the reports of Oille, Detweiler and Graham,[22] Miller,[23] Libman,[24] Biggs[25] and others. Pneumococcus endocarditis, which usually develops towards the end of a lobar pneumonia and most frequently involves the aortic valves, is almost

always fatal. Gonococcus endocarditis is likewise usually an ulcerative infection of the aortic valves and almost always fatal. Staphylococcus endocarditis usually occurs in association with abscesses of the heart muscle in the course of a septicemia as a terminal process. Not infrequently and indeed usually, all forms of acute bacteria endocarditis and especially those caused by streptococci, involve valves already the seat of chronic changes produced by the organism of rheumatic fever, whatever that may be. Streptococcus endocarditis may be acute and fulminating, ending fatally in two or three weeks, but in most cases the disease appears very insidiously with fatigue, evening temperature, etc., and is apt to pursue a prolonged subacute course with progressive ulceration, the production of embolism, anemia and emaciation. It is by all odds the commonest type of bacterial endocarditis and what follows here on the subject of chemotherapy applies mostly to this form of the disease.

Naturally enough, a large number of chemical agents have been tried, but it is hardly worth while reviewing them here because of the negative results. Arsenic, however, has held a prominent place for some years and sodium cacodylate (sodium dimethylarsenate) by intravenous injection is reported by Capps[26] to have probably benefited four of a group of eight cases. Bargen[27] thought that sodium cacodylate apparently had some beneficial influence on the healing of heart-valve infections of rabbits produced experimentally by intravenous injections of streptococci, and suggests that it may stimulate the endothelial cells of blood-vessels and blood sinuses to greater phagocytosis. Libman however, has as yet found no definite results with sodium cacodylate; Biggs states of thirty-five cases treated with the drug in daily dose of three grains by intravenous injection for eight to sixteen weeks, the mortality has been 51 per cent.; in another group not so treated the mortality has been 68 per cent. but that a longer period of observation will be required before the merits of the drug can be finally evaluated in these groups. It is also sometimes stated that large doses of the salicylates (2 to 6 drahms daily) are beneficial.

Blood cultures, and especially repeated cultures of at least 10 to 20 c.c. of blood, usually reveal the presence of the causative organism and particularly the streptococcus, although the patient may not present the usual symptoms of a septicemia, indicating that the bacteremia may be intermittent and due to a more or less mechanical sweeping of organisms from the valvular lesions into the blood without the organisms undergoing much proliferation in the blood. In my experience some focus of primary infection is usually to be found and should always be carefully looked for, especially abscesses at the roots of teeth or forgotten stumps and roots. It may be unwise, however, to extract such teeth at once; I recently saw a patient with *Streptococcus viridans* endocarditis who developed an exceedingly acute exacerbation ending fatally in three days following the extraction of three teeth with streptococcus abscesses. It may be well, therefore, to wait until the bacteremia at least has been checked before probable primary foci are disturbed and even then, I believe it is unwise to extract more than one or two teeth at a time in order that the consequent bacteremia may not be too severe. But a careful and thorough search for primary foci should always be made; in my opinion, the valvular lesions may be regarded as secondary foci with the possibility of being kept active by intermittent bacteremias from a primary focus in the teeth, tonsils, accessory nasal sinuses, etc. In this connection I may state, however, that primary foci must be treated separately from the heart lesion and preferably by extirpation. as no amount of gentian-violet,

mercurochrome or arsenic by intravenous injection appears capable of sterilizing apical abscesses or infected sinuses and tonsils.

In my experience, the intravenous injections of gentian-violet and neutral acriflavin in dose of 0.005 gm. per kilogram of weight, have been without influence upon the disease, even when given every three or four days for 3 or 4 injections. In one case, however, I believe that gentian-violet was the means for removing streptococci from the blood, but I have had no reasons at all for assuming that these dyes influenced favorably the valvular lesions. In my limited experience with three cases, repeated intravenous injections of mercurochrome have been apparently more efficacious insofar as immediate results were concerned; a chill, fever and diarrhea have usually followed the injections, but almost always the temperature has dropped to about normal for the following two or three days with marked improvement in the general condition. But the temperature then rises again and repeated injections are required. Naturally one hesitates to produce in these cases violent reactions of any sort, and especially anything favoring the production of embolism, but in my cases the chills and other symptoms of the mercurochrome reactions were apparently without harm. All three of my cases (streptococcus infections) ultimately succumbed; Young, Hill and Scott[27a] however have recently reported two apparent recoveries in a series of severe cases treated with mercurochrome by intravenous injection.

Antistreptococcus serum has been used extensively but without marked effects. I believe, however, that it may be useful during the acute stages when numerous streptococci are to be found in the blood; blood transfusion may be also beneficial and especially in the later stages when progessive anemia and emaciation develop and all of these methods may be summarized into the following *plan of treatment for Streptococcus endocarditis:*

1. During the acute stage marked by streptococcus bacteremia, 100 c.c. of antistreptococcus serum may be given intravenously with the usual precautions against anaphylactic shock. This dose may be repeated in forty-eight hours and thereafter 50 c.c. may be given by intramuscular injection every three or four days for an additional three doses. Serum sickness is almost sure to develop in a week or two, but is readily relieved by cautious doses of adrenalin (usually 0.5 c.c. of 1:1000 subcutaneously) and local applications. If bacteremia is not present, it is hardly worth while administering serum; likewise, in the subacute and chronic stages serum may be omitted, but in the acute early stages I believe it is worth while, even though the first blood culture may prove to be sterile.

2. Mercurochrome may be given instead of the serum or following the serum. The dose may be slightly reduced below the usual, like 15 c.c. of a 1-per cent. solution per 100 pounds; a second dose may be given four or five days later and usually in dose of 23 c.c. of a 1-per cent. solution per 100 pounds. As a general rule, the temperature drops within twenty-four hours after each injection, but generally rises again within three or four days when further injections are required. I have given one case as many as 6 injections without apparent harm to the kidneys, but one naturally hesitates in giving repeated injections of mercurochrome. Two doses, however, at intervals of three or four days may be regarded as quite safe. At this time another blood culture should be made. If streptococci are found, gentian-violet may now be injected intravenously in dose of about 30 c.c. of a 0.5-per cent. solution per 100 pounds; in one of my cases, an alarming cardiac depression followed but with recovery in a few minutes and no further reaction. These measures usually suffice for disinfecting the blood, but probably have but little or no disinfectant influence upon the valvular lesion. If, however,

measures of this sort keep the blood sterile, life is prolonged with increasing chances of gradual recovery and alternate injections of mercurochrome and gentian-violet may serve this purpose and are worthy of trial.

3. Insofar as the valvular lesions are concerned, it may be that healing is encouraged by the intravenous injection of arsenic and especially since some observers believe that this substance possesses dynamogenic effects, that is, the property of promoting fibrosis; furthermore, arsenic may promote phagocytosis by endothelial cells and clasmatocytes, as suggested by the work of Bargen. For these reasons, I believe that it is well to inject sodium cacodylate intravenously every other day in dose of about three grains for an adult, although, frankly, I have not yet observed that this drug produced any material therapeutic effect. This dose corresponds to approximately 0.2 gm. per 140 pounds, which is a safe amount, since the single maximum tolerated dose for the lower animals is at least 40 to 50 times this dose per kilogram of weight (for rats and rabbits from 0.15 to 0.2 gm. per kilogram). Or neoarsphenamin in dose of 0.3 gm. dissolved in 5 c.c. of sterile water may be injected intravenously twice a week, purely for the purpose of eliciting these possible effects of arsenic upon healing and phagocytosis and with no hope of securing a direct disinfecting effect. It may be also worth while to give an occasional injection of mercurochrome in dose of 10 c.c. of a 1-per cent. solution and I have followed up the first two or three large doses with several of these small doses at intervals of three days with the hope of favorably influencing the valvular lesions. What with injections of mercurochrome, gentian-violet and the arsenicals, the treatment is hard pushed but the gravity of the disease warrants and demands energetic measures in most cases; of course, good clinical judgment must be exercised in the choice of these agents, their doses and intervals of administration and the condition of the patient's enunctories must be estimated in a careful manner with special reference to the condition of the kidneys.

4. If, in the meantime, the streptococcus recovered in blood cultures or abscesses of the teeth is prepared in a vaccine, it may be worth while to give the patient a subcutaneous injection once a week, starting with a small dose like 50 million and gradually increasing. It is also a good plan to immunize a compatible blood donor, as the transfusion of 500 c.c. of blood, preferably by a direct method, not infrequently benefits the patient and is especially valuable for the support it gives in tiding the patient over a crisis or a prolonged septic infection. I have generally given my patients three or more transfusions for these effects, even though there is little or no hope of sterilizing the local valvular lesions by these means which must heal by natural processes aided somewhat by the measures here summarized.

Why it is that so little can be done for these cases is difficult to state. Off hand, one would suppose that the presence of gentian-violet, mercurochrome, etc., in the blood would have some sterilizing influence upon the lesions and especially by direct contact with the open ulcers even though the bactericidal concentration in the blood is only a matter of an hour or two following each injection; but the constant flapping of the valves deprives them of functional rest, which is the most important single factor required for recovery from inflammation. Apparently only the mildest of cases produced by streptococci of reduced virulence have a fair chance of ultimate recovery, although the disease may run a course of months or years. But if we could influence it enough to prevent ulceration, the changes of recovery are increased and I believe that every case should be given this chance despite the gloomy prognosis.

I have had no experience with mercurochrome, gentian-violet or acriflavin in the treatment of pneumococcus, gonococcus and staphylococcus endocarditis, but believe that treatment with these compounds in association with blood transfusions may be worthy of trial as a substitute for folding our hands and leaving the patient to his fate.

Chemotherapy of Pneumonia.—Needless to state, the chemotherapy of pneumococcus lobar pneumonia, so well designated the "captain of the men of death," has deservedly attracted a great deal of attention and, contrary to usual impressions, I believe that it has already accomplished a good deal and is worthy of a place in the modern treatment of this dreaded disease along with functional, regulatory, symptomatic and biologic therapy. Certainly there is no short cut specific treatment of pneumonia and the institution of a dietetic-hygienic regime, the expectant treatment of symptoms like cough, pain, dyspnea, insomnia and abdominal distention, as well as of the complications like severe toxemia, circulatory failure, jaundice, collapse at the crisis, profound asthenia, etc., demand appropriate treatment, in addition to and aside from what may be accomplished by specific biologic or chemotherapeutic measures.

Possibly too much has been expected of chemotherapy in this disease in the way of spectacular results in the form of immediate crises and no mortality. The most that can be expected is the destruction of pneumococci in the affected portions of the lung, to confine the process to the lobe involved, and to prevent the occurrence of empyema and septicemia, as well as complications resulting therefrom; in brief, to prevent direct or indirect extension of the pneumonia from the first focus of the disease. I doubt if any of our present chemotherapeutic measures are capable of penetrating and sterilizing the exudates of a pneumonic lobe, but I believe that there is considerable evidence in support of the hope that we may and do raise the pneumococcidal activity of the blood and lymph to such an extent that bacteremia and septicemia are corrected and prevented which materially aids in confining the infection to the lobe or lobes primarily involved and thereby preventing the successive involvement of fresh tissues with consequently a much greater chance of survival for the patient.

As reviewed in Chapter VI, quinin compounds including optochin base and ethylhydrocuprein hydrochlorid, have commanded most attention from the standpoint of chemotherapy and deservedly so, in view of their extremely high and somewhat selective pneumococcidal activity *in vitro* and encouraging results in experimental pneumococcus infections of the lower animals. Many excellent clinicians, including Da Costa, Aubrecht, Gibson, Solis-Cohen and others, have long believed that quinin exerts a favorable influence, and more recently Moore and Chesney,[28] Jakbo,[29] Schneider[30] and others have corroborated these views with optochin, the rather extensive literature being lately summarized by Cahn-Bronner.[31]

Unfortunately, optochin is capable of producing a toxic amblyopia in about 4 to 5 per cent. of cases, as reported in the literature, but when given by ingestion, as advised by Mendel, Moore and others, this complication is greatly reduced and may be entirely avoided by proper attention to dosage and intervals of administration. As stated by Solis-Cohen, tolerance for quinin is greatly increased in pneumococcus pneumonia, so that individuals with this disease readily withstand doses which would probably produce marked cinchonism in others. I am personally convinced that the following plan of chemotherapy, which is modified after that described by Solis-Cohen, Cahn-Bronner, Moore and others, is worthy of trial even though its value

cannot be stated in exact terms until more extensive clinical experience has been gained with it.

1. The intramuscular injection of 0.5 gm. quinin hydrochlorid with urethane, dissolved in 5 c.c. and injected as early as possible after the chill; 0.5 gm. of ordinary quinin and urea hydrochlorid dissolved in 2 or 3 c.c. of hot sterile water, may be used instead, it being necessary to attend to the following details in technic in order to avoid excessive local reactions: (1) to use a sterile solution containing no acid, (2) to prepare very carefully the skin and (3) to avoid depositing any of the solution in the subcutaneous tissues. If the fever does not fall within twenty-four hours, the injection is repeated. One then waits forty-eight hours and, if the crisis has not occurred, a third injection is given amounting to 1.5 grams within four days. The pharmacology, toxicology and further directions for injecting are given in Chapter VI.

2. Following these intramuscular injections of quinin, 0.15 gm. (2½ grains) of optochin hydrochlorid (ethylhydrocuprein) is given in capsules every three hours, totalling 1.2 gm. or 20 grains, for the purpose of maintaining the increased bactericidal activity of the blood. If injections of quinin cannot be given, optochin may be used instead on the first day in dose of 0.5 gm., followed every three hours by additional doses of 0.15 gm. each; commencing on the second day, the drug is given in dose of 0.15 gm. every three hours as just described. In either case the treatment is continued for three to nine days according to circumstances, but a careful watch is maintained for dimness of vision, which demands a cessation of optochin administration. Daily opthalmoscopic examinations for retinal ischemia are of distinct help in detecting the earliest evidences of amblyopia.

A careful study of statistics by Cahn-Bronner indicates that the mortality rate was only 6.4 per cent. for the cases treated with quinin, whereas in contemporaneous control cases, even after removing from the statistics patients who had entered the hospital moribund, the mortality was 20 per cent. Among the patients that received quinin injections within the first three days of the disease the mortality was only 5.7 per cent. There was noticed also a marked improvement in the general state of the patient (circulation and respiration). In pneumonias, other than those of pneumococcus origin, it is stated that quinin therapy produced no favorable effects.

As stated by Barker,[32] though even with the use of quinin and optochin the mortality rate in lobar pneumonia is still high, nevertheless the reduction indicated by the statistics given would make it seem worth while to make a trial of quinin therapy, at any rate until sufficiently large numbers of cases have been treated in different epidemics and in different places (with adequate controls) to establish the value or the worthlessness of the remedy.

Ochsner[33] believes that the internal administration of boric acid in dose of 5 grains three times a day is of benefit and recently mercurochrome has been used with apparent success by Freeman and Hoppe[34] and others in dose of 0.005 gm. per kilogram of weight. I believe that mercurochrome is especially worthy of trial in bronchopneumonias in which the etiological agent may be a streptococcus or some organism other than the pneumococcus, over which quinin and optochin have no beneficial influence, but even in severe lobar pneumonias (especially Type II infections) the compound has been apparently successful and especially worthy of trial when new lobes become progressively involved as indicated by a recent review by Young, Hill and Scott[34a] of 22 cases of broncho- and lobar-pneumonia treated with intravenous injections. The temperature sometimes falls within twenty hours after injection with an improvement in the general condition, but two

or three doses may be required at intervals of three to four days. Young and Birkaug have recorded the successful treatment of a case of streptococcus pneumonia by Martyn, who gave an intravenous injection of mercurochrome in dose of 0.005 gm. per kilogram, and in this type of pneumonia, the drug would appear to be especially worthy of trial. In addition to these chemotherapeutic agents, judicious biologic therapy in the form of injections of Type I pneumococcus serum or Huntoon's antibody solution are worthy of consideration and especially the latter in all Type II and III pneumonias.

Finally a brief mention may be made of efforts evolving a method for the disinfection of *pneumococcus carriers*. As shown by Dochez and Avery,[35] Stillman,[36] Sydenstricker and Sutton[37] and others, healthy individuals not in contact with cases of lobar pneumococci do not usually show the presence of the fixed types (I, II and III) of pneumococci in the upper respiratory tract, but among contacts they have been found in 6 to 40 per cent. Bearing in mind the numerous difficulties in disinfecting the mouth of pneumococci even with powerful and more or less specific antipneumococcus agencies, as ethylhydrocuprein and other quinin compounds, it is hardly to be expected that complete destruction of all pneumococci in the mouth and upper air-passages can generally be accomplished by this means, but for use among physicians, nurses and members of a family in intimate contact with persons suffering with lobar pneumonia, the systematic and daily use of washes prepared from 1:100,000 solutions of ethylhydrocuprein hydrochlorid or quinin bisulphate in 1:10 liquor thymolis may serve to destroy virulent pneumococci as they gain access to the mucous membrane of the mouth and upper part of the throat and prevent their proliferation in large numbers. In this manner and among such groups of persons, the systematic use of a mouth-wash of this kind held in the mouth and gargled in the throat for at least a minute twice or three times each day may aid in the prophylaxis of lobar pneumonia, as based upon the experiments conducted by Steinfield and myself.[38] Ethylhydrocuprein hydrochlorid by reason of its superior pneumococcidal properties is to be preferred, but may be substituted by quinin bisulphat or quinin hydrobromid, although these are not as powerful bactericides; solutions of either stronger than 1:10,000 are likely to prove objectionable to most persons. Liquor thymolis in itself appears to aid in the disinfecting process and is well borne in a 1:10 dilution, serving also to disguise to a large extent the bitter taste of ethylhydrocuprein or other cinchonic.

Chemotherapy of Pleuritis and Empyema.—Interest in the possibilities of local disinfection of the pleural cavities infected with pneumococci, streptococci, staphylococci, *B. influenzae,* tubercle bacilli or other organisms, has been greatly increased within the past few years and especially since the great pandemic of influenza in 1918, which was characterized by a high incidence of streptococcus pneumonias and empyemas. Some success has been attained in the chemotherapy of experimentally produced pleuritis among the lower animals and the subject is one of commanding interest and practical importance in the treatment of suppurative pleuritis of human beings.

Chemotherapy of Streptococcus Pleuritis and Empyema.—Experience during the past six years and especially with streptococcus empyema has shown that drainage by rib resection should not be done during the acute stage when the fluid is serous or seropurulent, because there are no, or but few, pleural adhesions and the resulting collapse of a large part of the lung adds materially to the mortality. For example, Rodman,[39] Stone,[40] Moschcowitz,[41] the Empyema Commission[42] and others have shown that too early resection of a rib or other surgical intervention is accompanied by a mortality

of 45 to 65 per cent. It is true that a number of closed methods for drainage have been devised by Mozingo,[43] Harloe,[44] Phillips,[45] Manson,[46] Churchman,[47] and Manson and Churchman have devised special means and apparatus for draining and washing out with Dakin's solution or gentian-violet under closed conditions; but it would appear that simple aspiration followed by the injection of gentian-violet, as advised by Major,[48] may be the method of choice in the treatment of acute empyema and Davis[49] has recently reported excellent results with a method conducted as follows:

"The chest over the fluid area is anesthetized with 0.5 of 1 per cent. novocaine. The aspiration is done with a 50 c.c. Luer syringe connected to the needle by a piece of rubber tubing two to three inches in length fitted with adaptors to fit syringe and needle. This prevents air entering the chest at the time of disconnecting syringe and needle and also is not likely to injure the visceral pleura and the lung by movements of the patient or by connecting and disconnecting the syringe. A nurse or assistant maintains the position of the needle. The fluid is aspirated until the cavity is almost dry, this to be determined by the patient beginning to cough. One precaution we have observed is that during the first aspiration if there is a large amount of fluid, that we did not take out an unnecessarily large amount, although we have never seen any bad results from slow aspiration. The one-half as much aqueous solution of gentian-violet (1:2500) as fluid removed is slowly injected into the cavity. The fluid is warmed to body temperature. By a later work of Churchman[50] we know that if the fluid is warmed above body temperature it has more of a bactericidal value. This fluid is allowed to remain until the next aspiration which should be done from one to five days, depending upon each individual case. During the second and following aspiration a solution of 1:1000 is used."

In subacute and chronic empyema with drainage by rib resection, irrigation with properly prepared neutral Dakin's solution with a free chlorin content of 0.4 to 0.5 per cent. would appear to be the method of choice, according to the results recently reported by Stevens.[51] Apparently the cavity becomes sterile more quickly than if treated by simple drainage without irrigation; the wound is cleansed and the exudate removed, and the excess scar tissue over the surface of the lung is dissolved, allowing the lung to expand and obliterate the cavity.

Stevens has emphasized the necessity of using properly prepared solutions. If they are too alkaline the tissues may be dissolved too quickly and thereby promote hemorrhage and the production of pleuropulmonary fistulas and if these are present at the time of thoracotomy, irrigation should be omitted or delayed; if the chlorin content is below 0.4 per cent., sterilization is faulty or may not occur at all. Hedlbom[52] has also reported favorable results from irrigation with Dakin's solution.

Irrigation every three hours is provided for by means of the Carrel tubes and best results are observed when irrigation is begun at once; thus when irrigation was instituted on the average of 90 days after resection and drainage, it required an average of 73 days for sterilization and an additional 71 days for healing making a total of 144 days; when irrigation was begun immediately after operation the time required for sterilization was 42 days with an additional 57 for healing or a total of about 98 days. Furthermore, the percentage of recurrences was materially decreased as likewise the percentage of thoracoplastic operations for the obliteration of cavities. Failures were ascribed to one of four things: (1) necrosis and infection of the resected rib; (2) a foreign body in the cavity (either a small sequestrum of bone, gauze or a drainage tube); (3) a pleuropulmonary fistula which caused constant reinfection of the sinus, or (4) sacculations and diverticula which could not be reached by the usual methods of irrigation. With these conditions remedied, sterilization was prompt.

Chemotherapy of Pneumococcus Pleuritis and Empyema.—As previously stated, most of the cases treated with simple aspiration and the injection of

gentian-violet or by rib resection, drainage and irrigation with Dakin's solution, were streptococcus empyemas, but the same methods are applicable for the treatment of pneumococcus and staphylococcus infections. Pneumococcus infections apparently respond even more rapidly since these organisms are more readily destroyed than streptococci. In acute pneumococcus empyemas, therefore, requiring the removal of pus, it would appear proper to aspirate during the acute or early stages and to inject gentian-violet as described above. A 1:1000 solution of ethylhydrocuprein hydrochlorid may be tried instead, being used in exactly the same manner and in the same dosage; but in my experience with two cases, apparently best results were secured by injecting a hot mixture of equal parts of 1:1000 gentian-violet and 1:1000 ethylhydrocuprein dissolved in sterile distilled water.

There is no danger of toxic amblyopia from the ethylhydrocuprein, as the amount injected in one day does not exceed 0.05 gm. which is perfectly safe, does not irritate the tissues and very materially increases the rate and degree of pneumococcidal activity. In cases requiring rib resection and drainage, however, preference is to be given to irrigation at three-hour intervals with neutral Dakin's solution, having a chlorin content of 0.4 to 0.5 per cent., although it may be worth while to use 1:1000 ethylhydrocuprein in place of the Dakin's solution once or twice a day for the purpose of increasing the rate of sterilization.

Chemotherapy of Staphylococcus, Tuberculous and Mixed Pleuritis and Empyema.—In staphylococcus empyemas the treatment may be exactly as decribed for streptococcus empyemas, but in any acute case of mixed infection with streptococci or pneumococci with Gram-negative bacilli like *B. friedländer* or *B. influenzae*, etc., it would appear worth while to aspirate and inject equal parts of 1:1000 gentian-violet and 1:1000 neutral acriflavin.

Chemotherapy of Scarlet Fever.—Since scarlet fever is now regarded as caused by a hemolytic streptococcus on the basis of the brilliant investigations of the Dicks, it is entirely likely that an efficient chemotherapy will be developed in time. Numerous reports by Lenzmann,[53] Laques,[54] Klemperer and Worta,[55] v. Boltenstern,[56] Lenzman,[57] Glaser,[58] and others indicate that intravenous injections of arsphenamin or neoarsphenamin may be distinctly worth while in the treatment of severe cases, as it would appear that the temperature is lowered along with a reduction in the incidence of complications and mortality. Since these arsenicals have been reported upon favorably in the treatment of other streptococcus infections and especially puerperal sepsis, they may be worth while using alone or especially in conjunction with the Dick or Dochez serum in the treatment of unusually severe cases. The dose of either for children may be from 0.1 to 0.3 gm. and for adults 0.5 to 0.6 gm. by intravenous injection; apparently arsphenamin (disodium salt) has given better results than neoarsphenamin.

Young and Birkhaug[59] have recently reported the successful treatment of an unusually severe case of scarlet fever complicated with erysipelas and septicemia, by intravenous injections of mercurochrome, and this compound may be quite worthy of trial in severe cases of scarlet fever, especially those showing the presence of large numbers of streptococci in the blood. As shown by Hirschfeller,[60] ethylhydrocuprein has no effect upon either scarlet fever or measles.

Chemotherapy of Meningococcus Meningitis.—Serum therapy has greatly reduced the mortality and incidence of sequelae in meningococcus meningitis and, to the best of my knowledge, chemotherapy has little or nothing to offer at the present time. If a bacteremia is present as detected

by blood cultures, it may be that intravenous injections of mercurochrome or neutral acriflavin may be of aid, but better results are secured by intravenous and intramuscular injections of antimeningococcus serum. Arsphenamin, neoarsphenamin, intramin, soamin, antimony tartrate, hexamethylentetramin (urotropin) and helmitol have been tried by intravenous or oral administration but with generally negative results. Most interest has been commanded by hexamethylentetramin because it is known to be capable of reaching the spinal fluid in meningitis when administered by mouth or intravenous injection, but its bactericidal activity depends upon the liberation of free formaldehyd and this does not occur in the spinal fluid because of its alkaline reaction; clinically the administration of this compound has not produced results even when given intravenously in doses as high as 60 grains for an adult.

Helmitol (hexamethylentetramin anhydromethylene citrate) is said to liberate formaldehyd in an alkaline as well as in acid media and while it possesses some bactericidal effects upon meningococci *in vitro*, yet it would appear impossible to administer sufficient by intravenous injection (60 grains) or by intrathecal injection (10 to 30 grains in an ounce of saline or horse serum) materially to influence meningococcus meningitis or to detect free formaldehyd in the urine or cerebrospinal fluid.

A variety of chemical agents like lysol, phenol, protargol and eusol have been injected intrathecally, but likewise without beneficial results; indeed, these substances may prove distinctly harmful. Thus, Flexner and Amoss[61] have found lysol and protargol harmful in experimental meningococcus infections of guinea-pigs and monkeys on account of their antileukotatic and antiphagocytic properties and since recovery from all forms of meningitis is largely due to phagocytosis, it is very important that nothing is injected capable of paralyzing this important process.

On the other hand, however, the oral administration of helmitol in dose of 15 grains every twenty-four hours is said to keep the cerebrospinal fluid under its influence and its administration may be helpful in the treatment of those fulminant and apparently serum resistant cases of meningococcus meningitis occasionally encountered. Furthermore, the intraspinal injection of neutral acriflavin in dose of 0.0001 gm. per kilogram (0.1 c.c. of 1:1000 per kilogram) mixed with the serum may be worth trying, although in a few cases in which this compound has been injected, the results have not been encouraging.

Chemotherapy of Pneumococcus, Streptococcus and Staphylococcus Meningitis.—Septic meningitis of otitic or nasal origin is one of the most dreaded of diseases since the mortality is about 100 per cent. with ordinary methods of treatment. I have never known streptococcus meningitis to develop without a primary focus of infection in the mastoid, accessory nasal sinuses or as a result of fracture of the skull, but pneumococcus meningitis may develope during lobar pneumonia or occasionally without a discoverable primary focus. Cases of this sort have a better prognosis and while the mortality in general for pneumococcus meningitis has been placed at about 93 per cent., yet I believe that in severe septic leptomeningitis of otitic or nasal origin it is about 100 per cent. when treated in the ordinary manner by spinal puncture and intraspinal injections of immune sera.

As stated in Chapter VI, Idzumi and I were sometimes able to save rabbits with experimental pneumococcus meningitis when ethylhydrocuprein (numoquin) was injected intraspinally within four hours after infection, but never when treatment was instituted after the onset of symptoms. In more recent experiments with streptococcus, pneumococcus and staphylococcus menin-

gitis of rats, rabbits and dogs conducted with the assistance of Miss Rule and Mr. Madden, I have found ethylhydrocuprein, gentian violet, neutral acriflavin, rivanol and mercurochrome ineffective when used alone after the development of symptoms.[61a] In these experiments the compounds were administered intravenously in dose of about 0.005 gm. per kilogram and also by intraventricular and intracisternal injection in doses varying from 0.0001 to 0.0004 gm. per kilogram, corresponding to a dose of 6 to 24 c.c. of 1:1000 solutions per 60 kilograms or approximately 130 pounds of weight. However, dogs infected by intracisternal injections of a Type I pneumococcus and a hemolytic streptococcus were frequently saved after the onset of symptoms by trephining and washing the ventricles to the cisterna magna with warm Ringer's or saline solution.

The diagnosis of septic meningitis of otitic or nasal origin is frequently difficult, that is to say, whether the meningitis is purely localized and aseptic with a favorable prognosis or a spreading and diffuse leptomeningitis. As a general rule spinal puncture is too long delayed and especially because many physicians fear to remove spinal fluid because of the possibility of setting up a meningitis by favoring the localization of organisms in the meninges from the blood. But I am quite sure that this danger is greatly over estimated and that the careful removal of 3 to 5 c.c. of fluid, ample for diagnostic purposes, is without harm.

In mastoid, lateral sinus or nasal accessory sinus infections it is usually an easy matter to discover the organism present in the discharges and it would appear to be good practice to attempt immediately passive immunization against the pneumococcus, if present, by the intravenous injection of 25 to 50 c.c. of Huntoon's antibody solution or against the streptococcus, by the injection of 50 c.c. of polyvalent antistreptococcus serum. Certainly these would appear advisable upon the first appearance of signs of meningitis when one is in doubt whether the infection is or is not localized.

I believe it is also well to attempt disinfection of the primary focus if this is at all possible; in mastoid cases, for example, infected clots may be removed and a rubber tube inserted into the wound for flushing every two or three hours with a mixture of equal parts of 1:1000 gentian violet and acriflavin. Dakin's solution may be used instead of the dyes, but it must be neutral and have available at least 0.4 to 0.5 per cent. chlorin. The disinfectant is readily introduced by means of a syringe attached to the tubing or by a douche bag and the fluid collected in large gauze pads frequently renewed. If the dyes are used it may be advantageous to dissolve them in 10-per cent. saline instead of water, as irrigation with hypertonic solution may reverse lymphatic absorption and promote better drainage. In some cases drainage tubes or silver wire have been introduced into the cisterna pontis through the internal auditory meatus after the destruction of the labyrinth with successful drainage of the localized infection. If these measures are taken before the exudate has become plastic it may be possible to irrigate the basal cisterna with Ringer's solution by the method of Eagleton,[62] needles being placed in the cisterna magna and lumbar region. In sinus thrombosis and phlebitis Eagleton also advises ligation of the internal carotid artery on the affected side to place the parts at rest and facilitate operative procedures. To be effective, measures of this sort must be instituted at an early stage, although Eagleton has abandoned his former method of continuous subarachnoid irrigation.

But I believe drainage is the most important factor of treatment. Dandy[62a] reports the recovery of three cases of septic meningitis by continuous drainage of the cisterna magna; Rainey and Alford[62b] have also recorded

the recovery of two cases of septic meningitis by the institution of continuous spinal drainage by laminectomy and the insertion of a small catheter into the subarachnoid space. Septic meningitis therefore, is to be looked upon as a surgical disease demanding radical measures since a fatal outcome is almost sure by the usual treatment of spinal punctures and the intraspinal injection of immune sera.

But chemo-sero-therapy may be useful as an adjuvant measure. Wolf and Lehman,[63] Rosenow,[64] Cordua[65] and others have reported apparently successful results in the treatment of pneumococcus meningitis by intraspinal injections of ethylhydrocuprein hydrochloride. I have used it in eleven cases, injecting daily or twice daily, 15 c.c. of a 1:500 solution after removal of spinal fluid, but without success insofar as mortality was concerned. It is possible that better results may be secured by injecting Huntoon's pneumococcus antibody solution intraspinally in dose of 15 to 30 c.c. along with subcutaneous or intravenous injections of 25 to 50 c.c. Wieder[65a] observed a good primary result with it and Ervin[65b] has recorded the recovery of a case treated in this manner. I have also observed a beneficial effect in one case. In streptococcus meningitis it may be worth while to inject gentian violet intraspinally in dose of 5 to 20 c.c. of a 1:1000 solution; Royster[66] has reported a case in which life was apparently prolonged by the injection of very small doses varying from 0.08 to 0.2 mg.

But I am sure that serum therapy alone by intravenous or subthecal injection is insufficient and the same may be stated of such chemotherapeutic compounds as ethylhydrocuprein, mercurochrome and the dyes. When administered intravenously they may remove organisms from the blood but do not appear capable of influencing favorably the meningeal infection. Furthermore, it does not appear possible to introduce sufficient by intraspinal, intracisternal or intraventricular injection to influence the mortality. It is necessary to promptly institute drainage along with lavage when possible and employ these other agents as adjuvants, if any success is to be gained at present in the treatment of septic leptomeningitis of otitic or nasal origin.

Chemotherapy of Lethargic Encephalitis and Poliomyelitis.—At present chemotherapy has nothing to offer in the treatment of lethargic encephalitis or acute anterior poliomyelitis. I know of one case of the former disease apparently greatly improved and aided in recovery by the intravenous injection of neutral acriflavin in dose 0.005 gm. per kilogram, but further experience is required before any opinion can be offered regarding its value in this disease. Since it is possible that streptococci may be of etiological importance in both diseases, it may be advisable to try not only acriflavin but mercurochrome by intravenous injection; Visher[67] had recently reported the prompt improvement of two cases of encephalitis, following the intravenous injection of 10 and 8 c.c. respectively, of a 1-per cent. solution of mercurochrome Young, Hill and Scott[67a] also record two cases of acute anterior poliomyelitis treated with mercurochrome by intravenous injection with apparently beneficial results.

Chemotherapy of Typhoid and Paratyphoid Fevers.—Although the early bacteremia and prolonged course of typhoid and the paretyphoid fevers would appear to offer exceptionally good opportunities for chemotherapeutic disinfection of the blood and lymphoid tissues, these diseases have not so far engaged much attention from the standpoint of chemotherapy. In part, this is due to the impossibility of producing the diseases in the ordinary laboratory animals for experimental investigations, although a temporary carrier state may be produced in rabbits. In all probability basic fuchsin would be a compound possessing some degree of bactericidal activity *in vivo*

for the bacilli of this group, but I have no knowledge of its being employed. Neutral acriflavin may be likewise worthy of trial, but in cases of early typhoid with positive blood cultures, I believe that one or two intravenous injections of mercurochrome in dose of 15 to 20 c.c. of a 1-per cent. solution for adults would be distinctly worth trial for attempting the disinfection of the blood and possibly of the tissues to such an extent, at least, as may reduce the duration and spread of the infection. Pond and Barrier,[68] state that the intravenous injection of this compound apparently shortened the duration of typhoid fever in 12 cases receiving one or two injections. Leitner[69] states that of 12 carriers of *Bacillus paratyphosus B* treated with one or two intravenous injections of neoarsphenamin in dose of 0.3 to 0.6 gm., 10 were apparently cleared up, but these results require confirmation.

Chemotherapy of Arthritis.—I have already discussed in Chapter VII the chemotherapy of experimental arthritis with the salicylates and related compounds. Their beneficial and curative effects in this disease cannot be satisfactorily explained at present, unless the etiological agent is an undiscovered organism much more susceptible to these compounds than are the various streptococci regarded as causing both acute and chronic forms of bacterial arthritis. Suffice to state that the administration of this group of compounds usually affords so much relief in acute rheumatic fever, at least temporarily, that the salicyls are commonly included in the list of specific drugs and various theories to explain their action have been discussed in Chapter VII. The toxicity, pharmacological action, methods of administration, etc., of the salicylates are so well known, however, that it is not required to review them here, but it may be well, at least, briefly to allude to some of the newer compounds advanced as substitutes for them in the treatment of arthritis.

Of these, phenylcinchoninic acid, better known as "cinchophen" or "atophan" and related to quinolin and salicylic acid, as well as the ethyl ester of paramethylphenylcinchoninic acid, better known as "neocinchophen," "novatophan" or "tolysin," are commanding considerable attention as indicated by the early reports of Heller,[70] Bendix,[71] Klemperer,[72] and Jokl,[73] who treated various types of arthritis with cinchophen or its derivatives. The three latter observers found neocinchophen especially beneficial in the treatment of the acute arthritis of rheumatic fever. Small doses were administered—rarely more than 3 gm. a day for from two to seven days—so that many of the patients were only partly relieved; and it was frequently necessary to change the medication to the salicylates. However, they found the drug less toxic than salicylates, and Jokl concluded that not only was this drug a good substitute for the salicylates in many cases of acute polyarthritis, but also it was to be preferred in those cases in which one hesitates to use it i.e., when rheumatic fever is complicated by nephritis, heart disease or gastro-intestinal disturbance.

The toxic effect of cinchophen was called attention to by Schroeder,[74] who reported 9 cases of his own of severe by-effects from the drug, and 8 other cases reported to him by other physicians and his patients. In his experience, the drug may produce irritation of the digestive tract, as well as constitutional symptoms of generalized itching, eruption and edema of the skin, fever, headache, etc. Hanzlik and his associates[75] found that both cinchophen and neocinchophen may produce injurious effects on the kidneys, as evidenced by albumin, casts and white blood cells in the urine, but that the effect is greater with the former drug. They also found that the symptoms of salicylism, such as nausea, vomiting, dizziness and tinnitus, may also accompany the use of these drugs.

One special advantage of cinchophen and neocinchophen over the salicylates is their effect in increasing the elimination of uric acid in the treatment of gout. The increased excretion begins almost immediately, but lasts only so long as the drug is continued; the increase is sometimes so great that uric acid is precipitated in the urine before it is voided. Clinically, however, both drugs are much less efficient in chronic gout than in acute arthritis and non-uratic joint affections. The dosage of cinchophen and neocinchophen is from 0.5 to 1 gm. (8 to 15 grins) three or four times a day; or 0.5 gm. every hour for six doses, with large amounts of water.

Plant,[76] Heubner,[77] Edens[78] and others have claimed good results in the treatment of arthritis with "maretin" and Engelen[79] and others with "melubrin" (the sodium salt of phenyl-dimethyl-pyrazolon-amido-methan-sulphuric acid), but neither has proved superior to the salicylates or cinchophen and have not commanded much attention. In my experiments solutions of "melubrin" as concentrated as 1:20 were without bactericidal effects for streptococci and staphylococci *in vitro* in exposures as long as two hours, and amounts as high as 0.3 gm. per kilo were without trypanocidal effects.

Special mention may be made of intravenous injections of mercurochrome in the treatment of infectious arthritis due to streptococci, pneumococci, staphylococci and the gonococcus. In some cases of acute arthritis with sterile blood cultures, the relief from pain and swelling is sometimes very pronounced. In gonococcus arthritis, however, the results have not been as good as in other types, although gonococcus bacteremias have been cured promptly and permanently. Young, Hill and Scott[79a] however, have recently stated that of twelve cases of gonorrheal arthritis treated with intravenous injections of mercurochrome, five were apparently cured with complete disappearance of the arthritis and initial infection. Strikingly good results were also reported in the treatment of four additional cases non gonorrheal in origin. In arthritis deformans the results have been generally negative and mercurochrome is of no value at all by intravenous injection in the treatment of primary foci of infection in the teeth, tonsils or elsewhere.

In *suppurative arthritis* of the knee caused by staphylococci, pneumococci and gonococci, Churchman[80] has irrigated with saline solution and hydrogen peroxid followed by hot 1:1000 gentian-violet for five minutes and finally with 1:10,000 gentian-violet which is left in the joint, by means of a special apparatus designed by him, and whenever a joint is opened for drainage, lavage with gentian-violet, acriflavin or a mixture of the two (1:1000 to 1:2000) may prove efficacious and especially in infections produced by the Gram-positive cocci. Mercurochrome in 1:1000 solution may be employed in the same manner. Whether or not aspiration with the injection of these disinfectants is worth while, I am unable to state; likewise, in tuberculous arthritis, the value of these procedures has not been determined, although lavage with gentian-violet by Churchman's method is worthy of consideration.

Chemotherapy of Tuberculosis.—The chemotherapy of tuberculosis is almost entirely at present in the experimental stage and I have already briefly discussed the situation in the preceding chapters in a review of the results observed with a large number of dyes, arsenicals, mercurials, copper and gold salts, the cerium earths, guaiacol and its congeners, etc., in the treatment of tuberculosis of human beings and the lower animals. Gold and copper salts have long maintained the places of primary interest in relation to the chemotherapy of tuberculous infections, but none have so far demonstrated sufficient curative activity to warrant their use in the treatment of tuberculo-

sis, although it is not to be denied that some are apparently capable of producing tuberculin-like reactions about tubercles which may prove beneficial, when frequently repeated and not excessive, by increasing the laying down of fibrous tissue and encapsulation. At this writing, sodium aurothiosulphate (sodium gold thiosulphate), better known as "Sanocrysin," is commanding attention by reason of the work of Møllgaard and his associates.[81] According to these investigators a dose of from 0.01 to 0.02 gm. per each kilogram of body weight has no harmful effect and these are the doses commonly employed along with an antiserum for preventing severe reactions believed to be caused by destroyed tubercle bacilli.

But the tuberculin-like reaction following the injection of the drug in tuberculous patients may be serious; numerous deaths have resulted, and clear-cut indications and rational dosage for the antiserum have not been established. Careful consideration of the results recorded of the "sanocrysin" treatment by the Danish clinicians reveals that it is of no value in miliary tuberculosis or in tuberculous leptomeningitis, and that in advanced and serious cases of pulmonary tuberculosis the treatment is perilous and offers "only a slight chance of recovery." Furthermore, in surgical tuberculosis, intravenous injection "has given no satisfactory results." It is apparent, therefore, that there is no justification for rushing this drug and the serum into the treatment of tuberculosis at the present time until they have been more thoroughly studied under well-controlled conditions, which investigations are now reported as being under way. My colleagues Schamberg, Harkins and Brown[81a] have recently found that gold compounds had some influence upon experimentally produced cutaneous lesions of rabbits with prolongation of life, but in no instance were cures effected.

Chaulmoogra oil, which is regarded as exerting a curative effect in leprosy, has shown no beneficial results in the treatment of experimental tuberculosis, as already reviewed in Chapter VII, but mention may be made of the report of Lukens,[82] indicating that it may be worthy of trial in the treatment of tuberculous laryngitis for the relief of pain and dysphagia. The oil is diluted to 10 to 20 per cent. with olive oil and two to three times a week from 0.5 to 1 c.c. dropped above and behind the epilogttis and finally on the cords by means of a syringe fitted with a metal eustachian catheter. Alloway and Lebensolm[83] state that daily treatments of this kind are useful in the majority of cases although they cannot entirely replace other forms of medication; Peers and Shipman,[84] however, state that, while slight temporary relief may follow and especially relief from dysphagia, caution should be exercised in selecting patients, as febrile cases may be influenced unfavorably.

In this connection mention may be also made of the effects of "sodium morrhuate," the sodium salts of the mixed fatty acids of cod liver oil, employed by Rogers and his colleagues in the treatment of tuberculosis by intravenous injection. Apparently slight febrile and focal reactions have been produced with improvement in some cases in the form of lessening of fever, cough, expectoration and numbers of tubercle bacilli, but specific tuberculocidal effects are not produced and the compound cannot be regarded as influencing tuberculosis more than cod liver oil itself.

Mention may also be made of the possibilities of chemotherapy in association with surgery in the treatment of large tuberculous pulmonary cavities as recently reported by Gekler, Lovelace, Rankin and Weigel.[85] Following the operations, a saturated solution of gentian-violet in 10-per cent. alcohol and distilled water was applied to the walls of the cavities by means of an atomizer; in some cases methylene-blue was applied after gentian-violet and they state that the latter brings away necrotic and sloughing tissue and that it will

definitely control the usual secondary infection to be found in a tuberculous cavity, and also kill off most of the tuberculous infection. Methylene-blue, following the gentian-violet, seemed to have an even more markedly deleterious influence on the tubercle bacilli, and its free use in a 4-per cent. solution did not damage the tissues or inhibit the process of repair. Furthermore, in one case, the cavity underwent rapid shrinkage and while this method of treatment is still in the experimental stage, since sufficient time has not yet elapsed to determine what will be the ultimate fate of these cavities, yet the work of Gekler and his associates is commendable and may open up a method for the chemical disinfection of tuberculous cavities of the lungs, not only by the method developed by them, but possibly also by means of direct aspiration and drainage with the application of disinfectants by means of the Jackson bronchoscope.

Arsphenamin and neoarsphenamin have also been employed in the treatment of tuberculosis and especially in tuberculosis of the skin and those cutaneous lesions of obscure origin known as "tuberculids;" I shall, however, discuss these subjects shortly in the section devoted to the chemotherapy of skin diseases.

Chemotherapy of Leprosy.—Naturally enough, in a disease of such antiquity as leprosy, numerous efforts have been made to develop or discover a specific remedy and a host of substances have been advocated, tried and discarded. At the present time chaulmoogra oil and the ethyl esters of its fatty acids are commanding most attention and, indeed, according to Warren[86] from whose excellent review of the recent literature I shall largely quote, in India and adjacent countries, chaulmoogra oil has been used both orally and externally in the treatment of leprosy since prehistoric times. However, it is so irritating to the intestinal tract that the oral dosage can seldom be pushed to the curative point in leprosy. It is a current belief among the natives of India that even if the digestive tract of a leper patient can withstand the chaulmoogra oil treatment the diseases can not always be cured, i.e., that chaulmoogra oil is not a specific in the treatment of leprosy.

The chemistry of true chaulmoogra oil was very exhaustively worked out by Power and his associates[87] a number of years ago. They found that the oil consists chiefly of the glyceryl esters of two or more new fatty acids, with a small quantity of palmitin and a phytosterol. The new acids isolated differ from any previously known fatty acids in containing a five-membered carbon ring with side chains of diminishing length as the molecular weight decreases. Also, they are unique in being optically active. They contain only one pair of doubly-linked carbon atoms; hence they absorb but two halogen atoms. The acids isolated were named respectively "chaulmoogric acid" and "hydnocarpic acid" by their discoverers and it is probable that the specific bactericidal and medicinal properties of these acids are associated in some way with their molecular constitution.

The literature on the use of chaulmoogra oil by oral administration in the treatment of leprosy is so extensive and controversial, that it is not profitable to attempt its review. The first use of the drug by subcutaneous injection appears to have been recorded by Tourtoulis[88] in 1899, who had employed it for several years with favorable results, but who did not consider the remedy a specific; Tourtoulis also used the drug intramuscularly with some success and shortly afterward Hallopeau[89] reported its use by the same method. According to Dyer, Blanc of New Orleans gave subcutaneous injections as early as 1888.

During the next decade the administration of chaulmoogra oil was still beset with difficulties. If administered by the mouth, nausea and digestive

disturbances may follow; if given subcutaneously, it is absorbed slowly since it is a heavy oil; by the intramuscular route, its administration is apt to be painful and sores are apt to develop due to slow absorption. At the present time the oral administration of the oil itself is seldom employed but preference given the subcutaneous injection of mixtures as advocated by Mercado and Heiser,[90] Heiser,[91] McCoy and Hollmann[92] and others. Rogers[93] had originally used the fatty acids of the oil by oral administration, but later employed their sodium salts (sodium gynocardate and sodium hydrocarpate) by subcutaneous and intravenous injection. Subsequently Rogers[94] was led to try the sodium salts of the mixed fatty acids of cod liver oil (sodium morrhuate) and Muir,[95] Carthew[96] and others have rendered favorable reports upon their value in leprosy. In 1918, however, Hollmann and Dean[97] advocated the subcutaneous and intramuscular injection of the ethyl esters of the fatty acids of chaulmoogra oil and this method is probably the most popular at present and particularly with the products improved upon chemically by McDonald,[98] Dean and Wrenshall.[99] Their latest work has been conducted with the esters prepared from the higher boiling fractions of the acids of chaulmoogra oil. These fractions have very high iodin and refractive index values which indicates that they belong to fatty acids which are relatively more unsaturated than the chaulmoogric series of acids. Since the hydnocarpic acid derivatives are believed to be somewhat more valuable in therapy than the corresponding chaulmoogric compounds, it is possible, as suggested by Warren, that acids of the chaulmoogric series of lower molecular weights would be still more efficient. Consequently one of the problems now open to the chemist is the synthetic production of acids of this series with shorter side chains and correspondingly lower molecular weights.

There are therefore, four main methods for the administration of chaulmoogra oil in the treatment of leprosy. In the *first* and oldest method the oil itself is given internally, but this has been largely abandoned because of gastric disturbances. Starting with a dose of 3 drops per day, it is said to be possible, however, to develop slowly a tolerance for as much as 15 drops per day. It is assumed that the emetic effects are due to local irritation, but it is a question whether almost as much nausea is not produced by any preparation of chaulmoogra oil by its central effect, irrespective of the method of administration, and oral administration is still favored by some institutions in India. It is quite possible to give by mouth weekly doses of oil, equivalent to 0.5 c.c. of the esters without producing extreme nausea or other toxic effects, but it is doubtful if oral dosage can be increased to equal that of subcutaneous injection of the esters.

In the *second* method the whole oil is injected subcutaneously, Heiser's mixture being usually employed:

Chaulmoogra oil	60 c.c. (f℥ii)
Camphorated oil	60 c.c. (f℥ii)
Resorcinal	4 gm. (gr. 60)

The mixture is sterilized at 100°C. and injected intramuscularly in ascending doses from 1 to as much as 10 c.c. at weekly intervals. Doses exceeding 5 c.c. however, are apt to produce abscesses. Reports by Hopkins,[100] Bercovits,[101] Coghill,[102] Hall,[103] Cadbury,[104] Connell[105] and numerous others, however, indicate that many apparent cures and improvements have been secured. Harper[106] has even injected the whole oil intravenously, employing a mixture of 500 c.c. of oil, 500 c.c. of ether and 1 gm. of iodin, the dose being from 10 to 20 minims at weekly intervals.

In the *third* method the soluble sodium salts of the total fatty acids of chaulmoogra oil are injected intravenously, Rogers employing a 3-per cent.

solution and injecting from 1/10 to 4/5 grain at weekly intervals. Unfortunately, however, phlebitis is sometimes produced as a result of a long series of injections.

In the *fourth* method the ethyl esters of the total fatty acids of chaulmoogra oil are injected intramuscularly or subcutaneously in doses of 0.1 to 1 c.c., Muir's formula being as follows:

Mixed ethyl esters		
Pure creosote	āā..	30 c.c. (f℥i)
Camphor		30 gm. (℥i)
Olive oil		75 c.c. (f℥ijss)

Some pain is produced, but by careful attention to technic in preparing the esters it is possible greatly to reduce local irritation by removing the irritating volative impurities. Perkins[107] employs a current of steam for two hours; in Calcutta they are removed by washing with sodium carbonate solution and in China by repeated distillations. Hollman[108] has recently described the Ball method for their preparation and Morrow, Walker and Miller[109] state that the butyl and propyl esters are less irritating than the ethyl esters. Read[110] has recently made a thorough study of the toxicity of chaulmoogra oil and its derivatives.

In addition the diet requires attention. Embrey[111] in working on the diet of lepers in the Philippines showed how marked a difference in body weight could be produced by giving attention to the vitamin and salt content of the food. Muir[112] lays particular emphasis on a diet rich in raw vegetables. The foods recommended have an alkaline ash and are rich in vitamins. Strychnin is principally of value in nerve leprosy and in nodular leprosy. The local lesions may be treated with electrocautery, *x*-rays, carbon dioxid snow or with local injections of the esters.

In conclusion, brief mention may be made of other substances in the treatment of leprosy. Thus Cawston[113] states that intravenous injections of tartar emetic are efficacious; Denney[114] has tried basic fuchsin; Takano[115] and Sugai[116] have used cyanocuprol and Hopkins[117] lists a large number of substances including tartar emetic, methylene-blue, bromids, vaccines, serums, etc. The mercurials have also been employed, the literature being reviewed by Denney and his associates[118] who have also reported that intravenous injections of mercurochrome, while not specific, aided in checking rapid retrogression of the disease. Arsphenamin and neoarsphenamin have been widely employed and the reports of de Vertenil[119], Sandes,[120] Chumokoff[121] and others as well as those of Gougerot,[122] Hasson[123] and others employing amino-arsenophenol, would tend to indicate that these arsenicals may be of some value. Not infrequently, however, syphilis is associated with leprosy and the administration of the arsenicals may give the impression of benefiting leprosy in such cases without affecting the leprous lesions themselves; on the whole nothing is to be expected in the treatment of non-syphilitic lepers with these compounds.

Chemotherapy of Anthrax.—In the chemotherapy of anthrax only those cases showing the presence of bacilli in the blood require consideration. This includes only a small fraction of cases of cutaneous anthrax, since prompt local treatment of malignant pustule usually results in an eradication of the disease. But all cases of internal anthrax are to be regarded as extremely dangerous at the outset. Blood cultures should be made on all cases irrespective of the size or location of the lesion. In one of my cases of cutaneous anthrax in whom bacteremia developed, the lesion occurred in a hair follicle of the skin of the thorax and was so small that it almost escaped detection.

In all cases of anthrax bacteremia, energetic treatment is required of the local lesion with intravenous injections of anti-anthrax serum and arsphenamin. The latter and neoarsphenamin are the only chemical compounds so far observed to exert a curative effect in this disease, although mercurochrome and gentian-violet by intravenous injection would appear to be worthy of trial. Becker,[124] Bettmann and Laubenheimer,[125] Mokrzecki,[126] Buberl,[127] Gsell,[128] Gasser[129] and numerous others have recorded cases of recovery ascribed to intravenous injections of arsphenamin or neoarsphenamin and I have already discussed in Chapter VII the results observed with these compounds in the treatment of experimental infections. Hutyra and Marck[130] also believe them worth trying in the treatment of anthrax of the lower animals.

For adults the dose of arsphenamin may be 0.6 gm. in alkaline solution injected intravenously in the usual manner; neoarsphenamin may be injected in dose of 0.9 gm. and it is usually advisable to repeat either dose in one or two days, making daily blood cultures.

Chemotherapy in Diseases of the Skin.—In a broad and general manner, diseases of the skin offer abundant opportunities for the practice of chemotherapy and especially if one accepts the local destruction of parasites, as in impetigo contagiosa, ecthyma, the trichophytoses, etc., as examples of chemotherapy in which medicaments are applied for parasiticidal effects without irritation or destruction of the body cells. I will admit that chemotherapy is not ordinarily thought of in the treatment of these purely local infections, but its principles are involved, nevertheless, although the importance of organotropism or the toxicity of chemical agents for the body cells is not nearly as great as when the medicaments are administered internally or by injection with consequently greater absorption. In some systemic or localized diseases with pronounced cutaneous lesions, as syphilis, frambesia tropica, gangosa, espundia, verruca peruana, leprosy and granuloma inguinale, chemotherapy plays a very important part and these diseases are separately considered in this or succeeding chapters.

Many of the local diseases of the skin, like impetigo contagiosa and ecthyma, are undoubtedly due to organisms, although the exact etiology has not been worked out; in these local disinfectants are of value in treatment. In others, like erythema multiforme, etiological studies strongly indicate a bacterial origin, while in others, like the herpetiform disorders and verruca, etiological studies indicate the operation of filtrable viruses, which so far have defied all efforts for identification, but against which the administration of chemical disinfectants by intravenous injection may prove of aid in treatment. In acne vulgaris, sycosis vulgaris and pyodermic infections in general, as well as in some of the eczemas and other scaly diseases, bacterial infection plays an important part and local applications of bactericidal compounds may be indicated in treatment; but these are so well known that it is hardly required or advisable to consider them in this treatise, although it may be stated in passing that the very multitude of such remedies to be found in books devoted to the diseases of the skin bears testimony to the fact that many are unsatisfactory and that the subject of cutaneous disinfection in these primary or secondary infections is one deserving of closer study and investigation from the chemotherapeutic standpoint.

Chemotherapy of Erysipelas.—A great number of substances have been applied locally in the treatment of erysipelas, a dermatitis and cellulitus caused by *Streptococcus erysipelatis*. Hot or cold local applications like saturated solutions of magnesium sulphat, lead water and laudanum, etc., may afford considerable relief even though there are no reasons for regarding them as bactericidal and capable of penetrating the skin and destroying the

streptococci in the cutaneous and subcutaneous tissues. It is possible, however, that saturated solutions of boric acid and solutions of mercurochrome may penetrate more deeply and I have used the following mixture with considerable success:

Saturated solution boric acid	400 c.c.
Alcohol (95- per cent.)	100 c.c.
Mercurochrome	0.5 gm.

This gives a 1:1000 mercurochrome in about 20-per cent. alcohol with the boric acid solution and the mixture is highly bactericidal for streptococci and staphylococci. Acriflavin may be used instead of mercurochrome in the same amount, but I believe that the latter yields somewhat better results. Either solution, hot or cold, should be frequently applied on lint or gauze and particularly at the margins where streptococcus activity is especially marked. Adams[131] has used a 5-per cent. water solution of brilliant green painted over the infected areas once or twice a day and states that beneficial results were observed in twelve cases. The discoloration can be removed in three or four days after subsidence of the infection by vigorous washing with ether soap. Of interest in this connection is the method of skin sterilization for operations practiced by Bonney and Browning[132] with a solution containing 1 per cent. of equal parts of crystal violet and brilliant green dissolved in equal parts of alcohol and water.

In severe cases, it may be necessary to administer antistreptococcus serum intravenously and Young and Birkhaug[133] have reported successful results following the intravenous injection of mercurochrome in dose of approximately 23 c.c. of a 1-per cent. solution per 100 pounds of weight. Young, Hill and Scott[133a] subsequently reported brilliant results in the treatment of seven additional cases and state that not a single failure has been brought to their attention. I have used gentian-violet by intravenous injection in dose of 30 c.c. of 0.5-per cent. solution per 100 pounds, but without success; in severe spreading infections it may be advisable, therefore, to use mercurochrome by intravenous injection and particularly if the infection cannot be brought under control by local applications and antistreptococcus serum. These measures are particularly indicated if blood cultures show that a septicemia is present. Rivanol (an acridin dye) and vuzin (a quinin compound) have also been employed by local application and intravenous injection, but I have had no experience with them in this disease.

Erysipeloid (Rosenbach) is not usually as severe as erysipelas and the etiology is doubtful, but it is very probably either a mycotic or bacterial infection in which saturated solutions of boric acid or the mixture of boric acid, alcohol and mercurophen described above, may be useful.

Chemotherapy of Cutaneous Tuberculosis and the Tuberculids.—In lupus erythematosis, Hachez[134] has reported the recovery of four cases following intravenous injections of neosilver arsphenamin in dose of 0.1 to 0.3 gm., two cases requiring eight injections before the lesions subsided. Stokes[135] states that of 20 cases with papulonecrotic tuberculids and erythema induratum treated with arsphenamin in conjunction with roentgen-ray and constitutional regimen, 17 were markedly benefited, with apparent cures in some. Many of these patients had a definite tuberculosis, the lymphadenitis in 9 cases being treated surgically without influencing the cutaneous lesions. Arsphenamin had no appreciable influence on adenitis and is believed to be contraindicated in acute febrile or rapidly progressing cases, but otherwise has shown a marked effect upon improving the general condition of the patients with an increase of weight, disappearance of rheumatic pains, etc.

Benoit,[136] Zauck and Pelbois,[137] Morin and Julia,[138] Ravaut[139] and others have likewise reported good results.

It is difficult to explain these effects but it is possible that intravenous injections, producing colloidal reactions and associated with roentgen-ray and sunlight exposures, may result in an increase of leukocytes and enzymes of the skin and blood responsible for the improvement in both the general health and cutaneous lesions. Whatever may be the mechanism, it would appear, however, that the intravenous administration of arsphenamin may prove quite helpful in the treatment of the tuberculids when combined with an improved regimen, roentgen-ray or other appropriate local measures. Needless to state, a host of substances have been employed by local application with indifferent success.

Chemotherapy of Pemphigus and Herpetic Diseases of the Skin.—As is well known the administration of arsenic is frequently beneficial in the treatment of dermatitis herpetiformis and both arsphenamin and neoarsphenamin have been administreed intravenously as substitutes for arsenious acid by ingestion, but to the best of my knowledge these compounds are of little or no benefit in the treatment of acute pemphigus. Merz,[140] Stumpke,[141] Wolfe,[142] Friboes,[143] Eschweiler[144] and others have reported favorable results, but it is possible that these occurred with bullous forms of dermatitis herpetiformis rather than with true "septic" pemphigus foliaceous and pemphigus vegetans, which are invariably fatal, although mild cases may develop remissions over a period of months. In such cases, my colleagues, Greenbaum and Schamberg, have administered mercurochrome intravenously, but, after the acute death of one case ascribed to this drug, have advised small and cautious doses like 10 or 15 c.c. of a 1-per cent. solution instead of the usual doses of 20 to 30 c.c. for an adult of average weight.

Now that herpes zoster and the various clinical types of herpes simplex are known to be caused by a virus as shown by the investigations of Goodpasture, Teague, Levaditi and others, it is to be hoped that chemotherapy may prove of aid and especially in the treatment of zoster, but at this writing no compounds have been evolved demonstrating a specific effect. With the assistance of Dr. Malcolm J. Harkins, I have produced herpetic lesions on the corneas of rats and given intravenous injections of arsphenamin, neoarsphenamin, mercurochrome, gentian-violet and acriflavin every three or four days in doses per kilogram equivalent to those ordinarily given to human beings, but the lesions did not appear to be affected or to heal more rapidly than the untreated controls. The ease with which the experimental lesions are produced, however, renders these infections readily approachable for chemotherapeutic experiments.

Chemotherapy of Mycotic Diseases of the Skin.—The chemotherapy of the mycotic infections of the skin, as the various ringworms or trichophytoses (tinea circinata, tinea tonsurans, tinea sycosis, tinea cruris, etc.), favus (achorion schoenleinii), tinea versicolor (microsporon furfur), etc., would appear to offer a particularly interesting and practical field for investigation. A host of substances have been advocated for the eradication of these infections and while some, like tincture of iodin, may be efficacious by reason of a direct mycocidal effect, others like salicylic and benzoic acids, which are the essential ingredients of the well-known Whitfield ointment, may owe their efficacy primarily to exfoliative effects. In these infections the problem would appear to be one of discovering a compound possessing a sufficiently high myocidal activity, combined with the property of penetrating the diseased skin and hair without irritation of the skin; doubtless exfoliation would greatly aid in the therapeutic effects.

Schamberg and myself[145] have conducted a number of tests with various dyes, mercurials and other substances incorporated in Sauboraud's medium to determine their relative efficiency in restraining the growth of various pathogenic molds (mycostatic tests) and also their relative efficiency in killing the molds (mycocidal tests); we observed that the two mercurial compounds (mercurophen and mercuric chlorid) exhibited the strongest myocidal effects with iodin ranking third. Among the dyes, brilliant green was most mycostatic but crystal violet proved distinctly superior as a myocidal agent. I have more recently observed that mercurochrome compares favorably with the other mercurials and because of its superior penetrating qualities I believe that it may prove worthy of use in the treatment of the various trichophytoses as a substitute for the widely used ammoniated mercury or mercuric chlorid; the following mixture has proved efficacious when employed along with the other well known local measures, the mercurochrome being finely ground before incorporation in the ointment:

Mercurochrome	gr. xxx (2 gm.)
Salicylic acid	gr. xx (1.5 gm.)
Benzoated lard	
Zinc ointment	āā ℥i (30.0 gm.)

Mercurophen may be substituted for mercurochrome and it is sometimes advantageous to employ solutions of mercurochrome, a 0.5-per cent. solution in 50-per cent. alcohol being usually well borne and penetrating deeply although objectionable for use on the exposed parts by reason of its color.

Chemotherapy of Diseases of the Eye.—In relation to chemotherapy, the diseases of the eye may be divided into two main groups, namely, (*a*) those of the deeper structures like the iris, lens, choroid, retina and optic nerve approachable only by the systemic administration of medicaments and (*b*), those of the lids, conjunctiva and cornea approachable by the direct application of chemical agents.

Insofar as the first group is concerned, the chemotherapy of congenital and acquired *syphilis* of the cornea, iris, retina, optic nerve, etc., is by all odds the most important and is separately considered, because the principles of the treatment of syphilis in general are involved and the whole subject is too important to permit of dismissal in a brief manner. In *rheumatic iritis* the internal administration of the salicylates and related compounds is usually beneficial and also belongs to this division as likewise, possibly, attempts toward the removal of uratic deposits by the administration of such drugs as cinchophen and neocinchophen. In *acute pneumococcus infections* it is possible that some beneficial effects may be secured by the internal administration of optochin (ethylhydrocuprein) hydrochlorid in doses ordinarily safe from the danger of producing toxic amblyopia, like 2 grains in capsules three or four times a day, the administration being along the lines previously discussed in the section devoted to the chemotherapy of pneumonia.

But aside from syphilis and rheumatic infections, chemotherapy has little to offer in the treatment of parasitic infections of the deeper structures. In *subacute and chronic gonococcus, streptococcus and staphylococcus iritis*, for example, it is hardly worth while to administer mercurochrome, gentian-violet, etc., because these compounds are not sufficiently penetrating or selective to reach and disinfect these local lesions, although in *acute and fulminating pyogenic infections* of these tissues, the intravenous administration of such compounds may be demanded and especially if the lesions are

associated with septicemia. Likewise in *tuberculous infections* of eye, chemotherapy has nothing to offer at present unless the gold compounds, now commanding considerable interest, should prove of value.

But when we come to consider the treatment of bacterial infections of the conjunctiva and cornea by the topical or local application of chemical disinfectants, we approach a most interesting and practical field in chemotherapy. In some mild infections the solutions applied need possess only cleansing properties, but substances possessing appreciable degrees of bactericidal activity are of distinct aid. The essential properties of a chemical agent designed for local application in infections of these structures has been discussed in Chapter III.

Owing to the brief contact between medicament and organisms, probably only a matter of seconds until the tears and inflammatory exudates dilute the chemical agent below a disinfecting threshold, frequent instillations are required and especially in the treatment of acute infections of the conjunctiva or cornea.

Needless to state, a very large number of agents have been advocated for local application in the treatment of bacterial conjunctivitis, keratitis, dacrocystitis, etc., but is not profitable to review their properties here in relation to chemotherapy. It would appear worth while, however, for the ophthalmologist to determine, if possible, the exact nature of each infection and select a chemical agent for disinfection according to the organisms present.

Ethylhydrocuprein Hydrochlorid in the Treatment of Diseases of the Eye.— Following the discovery by Morgenroth and Levy of the extremely high pneumococcidal activity of ethylhydrocuprein, Goldschmidt[146] reported some remarkable results in the treatment of pneumococcus ulcers of the cornea and as a prophylactic before operations, following local applications and instillations of solutions of this drug. Since then Gradle,[147] Puscarin,[148] Wyler,[149] Zentmayer,[150] Bedell[151] and numerous others have reported favorably upon the use of this compound, not only in the treatment of pneumococcus conjunctivitis and keratitis, but also in dacrocystitis and to some extent in other infections like gonococcus and streptococcus conjunctivitis, vernal conjunctivitis, trachoma and for the relief of photophobia in various ocular diseases.

The drug is usually employed in 1- to 2-per cent., solution applied directly to corneal ulcers or dropped into the eye. The powder itself has been rubbed into ulcers by Patton[152] with better results. Morgenroth and Ginsberg have found that 4-per cent. solutions in olive oil may be employed for corneal anesthesia and while the water 1- to 2-per cent. solutions are not usually painful, it may be necessary to first use an anesthetic when stronger solutions are employed. The drug has also been employed in the form of an ointment by Schwartzkopff (ethylhydrocuprein hydrochlorid, 0.1 gm.; atropin sulphate, 0.1 gm.; starch, 2 gm. and vaselin, 10 gm.). Gradle[153] states that the drug deteriorates rapidly in both solution and ointment and advises that a fresh solution be used every 5 to 7 days; this may account for the reports indicating that the drug apparently loses its curative effects when employed over long periods of time.

Bedell states that mixtures of ethylhydrocuprein and atropin, boric acid and zinc sulphate are compatible; I have found the same as likewise that the drug may be mixed with argyrol, silvol, neosilvol, gentian violet and acriflavin, but not with mercurophen or mercurochrome. In pneumococcus conjunctivitis and keratitis, I believe the following mixture is particularly efficacious when applied every 2 to 3 hours:

Ethylhydrocuprein hydrochlorid	1 gm.
Neosilvol	5 gm.
Water	100 c.c.

As stated by Zentmayer frequent applications (every 2 hours) are required in the treatment of acute infections and this is to be expected when it is remembered that the bactericidal effects are rapidly and sharply reduced by dilution with the tears and inflammatory exudates.

Best results have been secured in pneumococcus conjunctivitis and ulcerative keratitis; also in corneal ulcers due to trauma and as a prophylactic before operations upon the cornea. In low grade blepharitis, streptococcus conjunctivitis, gonococcus conjunctivitis, vernal conjunctivitis, trachoma, blepharospasm and photophobia, good results have been reported by some observers, although from my knowledge of its bactericidal effects I would not expect much therapeutic effect in infections other than those caused by pneumococci and related streptococci. Since dacrocystitis is frequently a pneumococcus infection, it is to be expected that the compound will prove of value in treatment after the primary causes like ethmoiditis, frontal sinusitis, hypertrophy of the turbinates, etc., have been corrected.

Mercurophen, Metaphen, Mercurochrome and the Dyes in the Treatment of Ocular Diseases.—Mercurophen and metaphen in 1:1000 solutions, have also proven of value in the treatment of pneumococcus conjunctivitis and keratitis. These compounds have a very high bactericidal action for the Gram-positive organisms including the pneumococci, streptococci, staphylococci and *B. xerosis*, and are to be recommended for use in the treatment of ocular infections due to these organisms; also for the prophylactic treatment of the conjunctiva and cornea before operations. As a general rule, 1:1000 solutions instilled every 2 hours produces no irritation, but on the contrary, usually prove soothing and slightly anesthetic. Mercurophen also possesses a high bactericidal activity for the gonococcus, *M. catarrhalis* and various other Gram-positive and negative organisms producing ocular infections. Mercurophen may be used in solution with either argyrol or neosilvol and I believe the following mixture is especially efficacious:

Mercurophen	0.01 gm.
Neosilvol	2.0 gm.
Water	100 c.c.

Mercurochrome may be employed in 1:500 solution as likewise gentian-violet or neutral acriflavin. Mixtures of neosilvol or argyrol with mercurochrome are compatible and may be employed; argyrol and neosilvol are also compatible with gentian-violet, but not with neutral acriflavin. Burnett and Gaus[154] and Clapp and Martin[155] have found instillations of mercurochrome in 1-per cent. solution efficacious in the treatment of gonococcus conjunctivitis of adults and the new-born.

Mercurophen and boric acid are incompatible, but mercurochrome and boric acid may be used together in the same solution and it is sometimes advisable to add 0.2 gm. to each 100 c.c. of boric acid solution for general use in the treatment of bacterial infections of the conjunctiva and cornea and for preparatory cleansing for operations.

Chemotherapy in Diseases of the Ear, Nose and Throat.—In the chemotherapy of diseases of the ear, nose, throat and accessory sinuses, most interest is commanded by the therapeutic efficiency of local applications of various chemical agents in the treatment of acute and chronic bacterial infections. In the treatment of syphilis of these organs, the general principles are the same as in the treatment of syphilis of other organs and the subject is of such

importance as to demand separate and detailed consideration. I have already discussed in this chapter the treatment of suppurative meningitis secondary to otitic infections and likewise the use of chaulmoogra oil in tuberculous laryngitis; also, in Chapter III, the principles of chemotherapy by the local or topical application of chemical disinfectants, which is a subject of particular interest in the chemotherapy of bacterial infections of these organs. Plaut-Vincent's angina is discussed in Chapter XXXIII.

Needless to state, a very large number of chemical agents and mixtures have been advocated for local application in infections of these parts, but it is not profitable to review them here in relation to the general subject of chemotherapy. Doubtless, most of them would be far more satisfactory if they could be applied more frequently and more thoroughly; undoubtedly the difficulty or practical impossibility of applying chemical disinfectants to the infected parts with sufficient frequency is largely responsible for the present unsatisfactory state of the treatment of otitis media and the infections of the various nasal accessory sinuses. Largely for this reason the treatment of ocular infections is on a more satisfactory basis; not because equally good disinfectants may not be used in otitic and nasal infections, but simply because they cannot be ordinarily applied in the latter with sufficient frequency. The matter of defective and insufficient drainage is also of great importance and especially in infections of the ear and nasal accessory sinuses. Therefore, it may be stated that in a broad and general manner the unsatisfactory results of local applications of disinfectants in bacterial infections of the ear, throat, nose and accessory sinuses is due not so much to a lack of suitable and efficient chemical disinfectants, as to the fact that they cannot be, or are not, applied with sufficient frequency and that drainage is frequently insufficient. Furthermore, the disinfectant frequently fails to reach the infected tissues altogether; possibly gaseous disinfectants, like chlorin, may improve results by reason of penetrating to parts not otherwise reachable under ordinary conditions. Experience indicates, however, that chlorin is not very beneficial in the presence of suppuration and collections of pus and has little to offer in the treatment of infections of the various accessory sinuses.

Chemotherapy of Nasal and Sinus Infections.—In my experience the majority of infections of the antrum of Highmore, ethmoid, sphenoid and frontal sinuses are due to pneumococci; in chronic infections, other organisms like *B. pyocyaneus*, staphylococci and diphtheroid bacilli may also be found in smears and cultures, but a pneumococcus is apt to be the primary etiological factor. Defective drainage and the difficulty or impossibility of applying disinfectants at frequent intervals would appear to be largely responsible for the unsatisfactory state of treatment by local applications, but insofar as the choice of disinfectant is concerned, I wish to call attention to ethylhydrocuprein hydrochlorid. This substance possesses an extremely high pneumococcidal activity in the presence of pus and can be counted upon to kill the organisms if brought in contact with them. Unfortunately, however, it does not penetrate deeply but may be combined with various other disinfectants to advantage in dose of 0.01 gm. dissolved in 100 c.c. of a saturated solution of boric acid, 5-per cent. neosilvol, 1:1000 gentian-violet or 1:1000 neutral acriflavin. Unfortunately, mixtures with mercurophen and mercurochrome are not compatible.

Mercurophen in 1:1000 solution is also highly bactericidal for pneumococci, streptococci, staphylococci, *B. friedländer*, diphtheroid bacilli and *B. pyocyaneus* and has proven useful in the treatment of these sinus infections; 1:1000 solutions of mercurochrome, metaphen, acriflavin or gentian-

violet in water are likewise useful and well borne, and both mercurochrome and the two dyes may be prepared to advantage with a saturated solution of boric acid instead of water. Freshly prepared Dakin's solution containing 0.4- to 0.5-per cent. of chlorin is especially useful when the pus is very thick and it is sometimes advantageous to increase its bactericidal effect by adding 0.01 gm. of mercurochrome to each 100 c.c. Chloramin-T in 2-per cent. solution is somewhat more stable and its bactericidal action more prolonged; mercurochrome may be added if a higher bactericidal effect is desired. It is sometimes efficacious to cleanse the infected parts with Dakin's solution or chloramin-T and to follow with applications of ethylhydrocuprein, mercurophen or mercurochrome in dose of 0.01 gm. dissolved in 100 c.c. of 5- to 10-per cent. neosilvol. If gentian-violet or neutral acriflavin are used alone the solutions may be stronger, as 1:200 to 1:300; gentian-violet may be used with neosilvol, but acriflavin is incompatible.

In rhinitis and ozena frequent instillations of 2- to 5-per cent. solutions of dichloramin-T in olive, almond or paraffin oil may be employed; if argyrol or neosilvol is used, it is sometimes advantageous to render them more bactericidal by adding 0.01 gm. of either mercurochrome or mercurophen to each 100 c.c.

Chemotherapy of Diseases of the Throat and Ear.—The treatment of *Plaut-Vincent's angina* with arsphenamin and congeners is considered in Chapter XXXIII, and the subject need not be considered here with much detail. In severe infections, however, and those proving resistant to treatment with arsphenamin or one of its substitutes, additional measures may be required. For such cases 1:200 solutions of gentian-violet or neutral acriflavin, 1:500 mercurophen, 1:100 mercurochrome or 7 per cent. chromic acid may be used locally by direct application after preliminary cleansing with hydrogen peroxid; due care should be exercised against swallowing these compounds, although there is but little or no danger from poisoning. Frequent applications are required, every two or three hours, until the disease is brought under control and in severe cases, preliminary cleansing with saline solution, diluted hydrogen peroxid or Dakin's solution may be required for removing the exudates. Of interest in this connection is the report by Sutton[156] of a case of Vincent's angina developing in a syphilitic under treatment with intramuscular injections of sulpharsphenamin and indicating that better results are to be obtained by local applications of arsphenamin or one of its substitutes.

In staphylococcus, streptococcus and pneumococcus *tonsillitis* and *pharyngitis*, mercurophen or metaphen applied either in the form of a gargle, atomizer or direct application affords quick relief. For the atomizer or for gargling these compounds may be employed by dissolving 0.2 gm. in 100 c.c. of *liquor antisepticus* and diluting one part with four or five parts of water; there is no danger from swallowing small amounts, although this should be avoided. For local application by the physician I believe a mixture prepared by dissolving 0.1 gm. mercurophen in 50 c.c. of water and adding 50 c.c. of glycerin is better than a water solution. If it is desired to use boric acid, a mixture prepared by dissolving 0.1 gm. of mercurochrome and 1 gram of boric acid in 50 c.c. of water and adding 50 c.c. of glycerin, may be recommended; unfortunately mercurophen is not compatible with boric acid.

Neutral acriflavin in 1:250 solution is also useful and the compound may be employed in the form of troches. Churchman and Herz[157] and Saurman[158] have employed solutions of gentian-violet for the treatment of *diphtheria bacillus carriers*, a 2 per cent. solution being thoroughly applied by spraying four times a day after preliminary cleansing with saline. The

patient and family should be informed that the dye, though staining everything with which it comes in contact, will not leave any permanent discoloration of the skin, mucous membrane or teeth.

I have had no experience with gentian-violet in the treatment of diphtheria carriers, but, in coöperation with Woody and Yagle,[159] have tried 1:250 solutions of brilliant green applied to the throats, noses and ears of carriers three times a day. Browning[160] states that solutions of this compound sprayed over the fauces, tonsils and pharynx three times daily for a week, succeeded in eliminating diphtheria bacilli from the throats of carriers, but in our experience the disappearance of the bacilli was only temporary. Brilliant green and gentian-violet, however, are highly bactericidal for bacilli of the diphtheria group and in 1:200 solution may be worthy of use in the treatment of these and staphylococcus infections of the ear, nose and throat. Gray and Meyer[161] have recently observed that applications of 0.5- to 2-per cent. solutions of mercurochrome may materially reduce the duration of diphtheria bacilli in the nose and throat.

Abraham[162] has recently recommended gentian-violet very highly for the treatment of streptococcus infections of the pharynx, tonsils and larynx; also for the treatment of Vincent's angina and infections of the external and middle ear and mastoid. It would appear, therefore, that gentian-violet, acriflavin, mercurophen, mercurochrome and ethylhydrocuprein hydrochlorid are all worthy additions to the usual chemical disinfectants for the treatment of bacterial infections of ear, nose, throat and accessory sinuses. Callison[163] has reported good results from local applications of 1-per cent. mercurochrome in the treatment of otitis media and other otitic suppurations. Special mention may be made of the beneficial effects of mercurochrome by intravenous injection in severe *mastoiditis* and *lateral sinus* infections with septicemia or threatened infection of the blood and meninges. Injections are usually possible even in young children and single doses have been reported as bringing about prompt and marked improvement.

Chemotherapy of Diseases of the Digestive Organs and Peritoneum. The chemotherapy of bacterial diseases of the digestive organs is a subject of commanding interest presenting numerous problems of considerable academic and practical importance. The treatment of syphilis of these organs is in itself a broad subject and is considered separately in Chapter XLXV, with special reference to syphilis of the liver; the chemotherapy of amebic dysentery and other protozoal and metazoal infestments is considered in Chapter XXXIII.

Chemotherapy of Diseases of the Mouth.—In *thrush* or other mycotic infections applications of 1:200 solutions of neutral acriflavin have been recommended by Maier[164] and others; gentian-violet also yields good results in the same strength. For severe and intractable cases, 1:500 mercurochrome or 1:1000 mercurophen may be applied locally, although proper attention to dietary errors and hygiene along with cleansing with simple boric acid solution, are generally sufficient.

In my experience, local applications to aphthous *ulcers* of the tongue and cheek showing no organisms in smears or cultures other than the common mouth bacteria, are of little or no use, since the underlying causes is in the lower tract; excessive smoking, etc., require correction. Needless to state, syphilitic ulcers and mucous patches as well as ulcerous epitheliomata are not benefited by local applications, the former usually disappearing rapidly under appropriate antisyphilitic medication.

Chemotherapy has nothing to offer in the treatment of *apical abscesses of the teeth;* apparently extraction and drainage are required for their eradication. Even repeated intravenous injections of mercurochrome, gentian-violet and acriflavin are without appreciable effect upon these areas of local infection, largely because the compounds are lacking in penetrability and selective affinity.

I have considered the treatment of spirochetic *gingivitis* with local applications of arsphenamin and its substitutes in Chapter XXXIII. The treatment of these infections is practically a speciality in dentistry worthy of support on the part of both the medical and dental professions, since most cases require appropriate surgical treatment in addition to the judicious application of disinfectants. Needless to state, a host of substances are in common use and particularly tincture of iodin. The dyes are unsuitable because of staining, but local applications and injection of the pyorrheal pockets with 5-per cent. dichloramin-T in oil, 1- to 3-per cent. solutions of mercurochrome as reported by Darnall,[165] 1:500 mercurophen, etc., in addition to a similar employment of 2-per cent. solutions of arsphenamin, are all measures of recognized value when properly employed. For the treatment of very mild and superficial infections and for prophylactic use after recovery, I believe that my tooth paste of arsphenamin and mercurophen, described in Chapter XXXIII, has proved of value when used once or twice daily as a substitute for ordinary dentrifices.

Chemotherapy of Diseases of the Liver and Gall-tract.—Unfortunately, the possibilities of treating cholangitis, cholecystitis and hepatitis of bacterial origin by the administration of drugs eliminated in the bile, has not commanded as much attention as demanded by the frequency and seriousness of these diseases. Just as it is possible to influence pyelitis and other infections of the kidney and genito-urinary organs by the administration of mercurochrome and hexamethylamin, by reason of their elimination by the kidneys and raising the bactericidal activity of the urine, so it may be that compounds will be produced capable of raising the bactericidal activity of the bile to a therapeutic threshold for the chemotherapy of infections of the gall-tract with streptococci, staphylococci, *B. coli*, *B. typhosus* and other organisms. Mercury compounds would appear to be of promise, because they are usually eliminated in an active bactericidal state. But the doses of ordinary mercurials are so small, in order to avoid toxic reactions, that it is doubtful if sufficient may be given appreciably to raise the bactericidal activity of the bile. Mercurochrome, however, is of greater promise in this direction, because of the possibility of giving larger doses by reason of its toxicity being at least ten to twelve times less than mercuric chlorid and similar compounds. Hill and Scott[166] have recently studied this subject in experiments employing rabbits and state that mercurochrome is excreted by the liver and renders the bile bactericidal for typhoid and cholera bacilli. In their opinion mercurochrome has cured rabbits that had been made gall-bladder carriers of typhoid bacilli and they believe this drug meets the requirements of a biliary antiseptic, since its toxicity is low enough to allow its safe clinical use intravenously or by mouth. It is suggested that the trial of mercurochrome clinically in both latent and acute gallbladder infections is not only justified but also clearly indicated from these experimental findings.

With the assistance of Miss Anna Rule, I have administered mercuric chlorid, mercurochrome, hexy-resorcinol and arsphenamin to rabbits by ingestion and intravenous injection and have studied the bactericidal activity of the bile for streptococci, staphylococci and *B. coli* but without constant or striking results. Our plan was to administer the

drugs to rabbits by intravenous injection or by stomach tube and two hours after the last dose to etherize each animal and aspirate the bile under sterile conditions. Each specimen was divided into three parts and seeded with broth cultures of a hemolytic streptococcus, *staphylococcus pyogenes aureus* and *B. coli;* the mixtures were kept at 37°C. and subcultured at the end of 10 and 60 minutes and again at the end of 24 hours. The drugs and doses were as follows:

(a) Mercurochrome, intravenously, single doses of 0.005 to 0.025 gm. per kilo.

(b) Mercurochrome, by stomach, three doses per day for three days of 0.005 gm. per kilo.

(c) Hexy-resorcinol, by stomach, three doses per day for three days of 0.05 gm. per kilo.

(d) Mercuric chlorid, by stomach, three doses per day for three days of 0.001 gm. per kilo.

(e) Arsphenamin, intravenously, single doses of 0.01 to 0.05 gm. per kilo.

Numerous untreated controls were included and the sterile bile was found frequently to be bactericidal for the streptotoccus even in 10 minutes. The bile of mercurochrome treated animals was occasionally more bactericidal for all three organisms than the bile of normal control rabbits and especially in exposures of one and twenty-four hours but hexy-resorcinol, mercuric chlorid and arsphenamin yielded entirely negative results. I am mentioning our results here, however, to indicate that by experimental methods it is possible to study this interesting problem and that chemotherapeutic research along these lines may succeed in evolving drugs eliminated in sufficient amounts and in a sufficiently active state, to raise the bactericidal titer of the bile to a therapeutic threshold for the treatment of bacterial infections of the gall-tract and liver, including gall-bladder carriers of typhoid bacilli. Compounds largely eliminated in the bile are of most interest and it is possible that cholecystography may be of assistance in work of this kind along the lines developed by Graham, Cole and Copher[167] with tetrabromphenolphthalein.

Chemotherapy of Bacterial Diseases of the Gastro-inestinal Tract; Intestinal Antisepsis.—Naturally, the question of chemical disinfection of the gastro-intestinal tract, and particularly of the colon, has commanded a great deal of interest and attention, not only in reference to the treatment of specific bacterial infections like typhoid fever, cholera and bacillary dysentery, but likewise in relation to other forms of ileo-colitis of bacterial origin and to the possibility of preventing the production of bacterial toxic products commonly regarded as responsible for some forms of "intestinal toxemia," arterio-sclerosis and hypertension, and possibly even of focal infection of the joints and other organs.

The subject may be divided, therefore, into two main divisions, namely, (*a*) chemical disinfection of such specific organisms as typhoid, paratyphoid, cholera and dysentery bacilli and (*b*), the reduction or eradication by chemical disinfection of organisms usually present, but increased for some reason to pathogenic proportions, with special reference to bacteria of the *B. coli* group. The difficulties are many and diverse. The stomach may be readily enough washed out with disinfectant solutions and the oral administration of such disinfectants as mercurochrome, mercurophen, gentian-violet, acriflavin, etc., must surely exert some bactericidal effects, but whether or not all organisms protected by the folds of mucosa are removed is open to question, although the subject of gastric disinfection is not one of much therapeutic importance except in relation to the passage of tubes into the duodenum for the purpose of securing bile and duodenal contents for bacteriological examination. Likewise, partial disinfection of the colon may be accomplished by frequent colonic irrigations with bactericidal solutions, but to be effective special methods and skill are usually required and re-infection soon follows.

But disinfection of the small and large intestines by the oral or intravenous administration of drugs has not been accomplished, although out of the host of compounds advocated for intestinal disinfection possibly trimethylomethyloxyphenol ("trimethol") and dimethylomethoxyphenol ("dimethol") are deserving of consideration, in view of the reports of

Roberts[168] and others of their beneficial influence in colitis. But while the proteolytic and aciduric groups may be influenced by diet and probably reduced by disinfectants or the administration of cultures of *B. acidophilus*, complete sterilization of the intestines is probably impossible as indicated by the work of the Dragstedts and Nisbet[169] with isolated loops of dog intestine treated with ether, alcohol (70-per cent.) lysol (2-per cent.), silver nitrate (5-per cent.) saturated solution of zinc chlorid, phenol (5-per cent.), saturated solution of salol, thymol (10-per cent.) camphor, menthol, Dakin's solution, betanaphthol, saturated solution of quinin sulphate and mercuric chlorid, all of which failed to effect complete disinfection. Despite the fact that this procedure offers a far more direct opportunity for bactericidal effects to manifest themselves than the usual oral administration of disinfectants could possibly permit, sterilization was in no case secured. In spite of the favorable conditions of these experiments, it was not possible to prevent the intestinal toxemia associated with stasis. At present, therefore, no experimental justification can be cited for the clinical use of antiseptics intended to produce intestinal antisepsis by direct action on the microorganisms that inhabit the gastro-enteric tract, insofar as complete disinfection of typhoid, dysentery and other pathogenic organisms are concerned, although it may be possible to reduce the usual flora.

But it is possible that future researches will produce chemical agents capable of partially disinfecting the gastro-intestinal tract of the usual proteolytic and aciduric floras and totally of such foreign organisms as the dysentery bacilli, when administered by oral administration or duodenal lavage. The latter method of administration is of course more promising of success, because of the large amount of fluid that may be introduced, but it is sharply limited in its clinical applications. It may be possible, however, to secure some degree of local disinfection of the intestinal tract through the action of drugs eliminated in the bile and by the intestinal mucosa in an active bactericidal state. The full- or half-complex compounds of mercury or other heavy metals, for example, may be utilized for such purposes on the basis of elimination practically unchanged before ionization or dissociation has occurred following intravenous or intramuscular injection. But unless the compound were endowed with an extremely high bactericidal activity along with an extremely low toxicity for the body-cells, it would be impossible to administer sufficient amounts capable of materially influencing the enormous bacterial flora of the intestinal contents. Unfortunately, it would appear at present that compounds of mercury and other heavy metals possessing a low organotropism or toxicity for the body-cells, by reason of slow ionization or dissociation of the metallic ions, are likewise of reduced parasitropic activity; in other words, both toxicity for the host and toxicity for the parasites is reduced in full- or half-complex compounds of slow dissociation, although a way and means may be found for evolving compounds of low toxicity for the body-cells while possessing a sufficiently high bactericidal activity to be of therapeutic efficiency. Mercurochrome, for example, approaches this ideal more closely than other mercurial compounds and may be eliminated in the urine in bactericidal amounts following the administration of non-toxic doses.

With the assistance of Miss Rule, I have studied the effects of this compound, as well as of hexy-resorcinol and mercuric chlorid (as a control), on the gastro-intestinal flora of rabbits. Our plan was to administer the compounds according to body weight during a period of fasting in the same amounts and by the same routes listed on page 180 and then two hours later open the abdomen under ether anesthesia for bacteriological examinations. For these purposes the stomach was tied off and 10 c.c. of sterile saline injected, mixed about, withdrawn and plated. Similar tests were conducted by tying off 5 cm. of

duodenum, ileum and ascending colon and securing material in the same manner. Control animals kept under identical conditions were cultured at the same time and the results compared with those observed among the treated animals. The results have indicated that mercurochrome by oral and intravenous injection may slightly reduce the numbers of bacteria in the small, but not in the large, intestines of rabbits. The results may not have a direct clinical application at present, but I am mentioning them here in this brief manner to indicate the possibilities of chemotherapeutic research along these lines.

It is not at all unreasonable to hope for the synthesis of compounds capable of influencing bacilli of the typhoid-dysentery group either by enteral or parenteral administration; in bacillary dysentery we have the additional means of reaching the infected tissues by colonic irrigation. Indeed, I am rather inclined to believe that the oral administration of mercurochrome and possibly of trimethol and dimethol, may be worthy of attention from the standpoint of reducing the intestinal flora to a point of therapeutic efficiency and in the treatment of bacillary dysentery and other forms of colitis; possibly much may be accomplished by *frequent* irrigations with a cleansing solution followed by the injection of such compounds as mercurochrome (:3000), mercurophen (1:5000), metaphen (1:5000), acriflavin (1:3000), gentian-violet (1:3000) or acid fuchsin (1:3000). Even though solutions of these strengths were used in amounts of 2000 c.c. and retained for ten or fifteen minutes, which would be desirable, toxic effects need not be feared from either local irritation or absorption, since the larger part is returned, although it would be advisable to follow the mercurials with a second cleansing irrigation. The mercurials in these strengths are bactericidal for both Gram-positive and Gram-negative organisms, but gentian-violet would be effective principally against the Gram-positive aërobes and anaërobes, while acriflavin and acid fuchsin would be effective especially against the Gram negative bacilli.

Chemotherapy of Peritonitis.—Under this heading, I refer to the possibilities of chemical disinfection of the peritoneum following the rupture of typhoid ulcers, gangrenous appendices, shot and stab wounds of the stomach and intestines, etc., that is, the acute generalized contaminations and infections. In operations upon cases of this kind, it may be advisable to wring out the towels and gauze brought in contact with the intestines and parietal peritoneum with weak solutions of disinfectant instead of plain saline solution, like a hot 1:5000 solution of mercurochrome in saline solution; likewise, to employ a solution of this kind for flushing the peritoneal cavity at the close of the operation. Equal parts of 1:2000 solutions of gentian-violet and neutral acriflavin may likewise prove serviceable. Under these conditions, solutions of these strengths are highly bactericidal for both Gram-positive and negative bacilli and cocci including the anaërobes; furthermore, they act quickly, which is an essential requirement. Judging from experiments with rabbits, they are not irritating or antiphagocytic and even should amounts up to 1000 c.c. be retained in human adults, which is advisable, they are not to be feared from the standpoint of toxicity. For example, 1000 c.c. of 1:5000 mercurochrome contains 0.2 gm. of compound and for an adult of approximately 135 pounds of weight this amount would be about 0.003 gm. per kilogram, which is less than the full dose by intravenous injection (0.005 gm. per kilogram). Furthermore, the absorption of this amount may aid in preventing septicemia and in any event, a careful watch for this complication should be maintained with the aid of blood cultures, and mercurochrome or gentian-violet administered intravenously, as previously described, if positive cultures are observed. The dyes are even less toxic. It may not be possible to sterilize the peritoneal cavity completely in this manner, but the infection is very probably reduced numerically and this may be sufficient for insuring a

successful outcome. Young, Hill and Scott[169a] state that intraveous injections of mercurochrome may be of some aid in the treatment of postoperative peritonitis.

I do not presume to advise surgeons upon the important topic of when and when not to irrigate and I realize that in localized peritonitis with complete or partial walling off irrigation may be harmful and is to be avoided; but when irrigation is possible, I believe that something more may be accomplished by using solutions of this kind than is secured by using plain sterile water or saline solution. Unfortunately, frequent irrigations of the peritoneal cavity every two or three hours, by means of the Carrel tubes or modifications of these, may not be possible because of shock, pain, excessive peristalsis, etc., but, in the presence of suppurative peritonitis or extensive soiling of the peritoneal cavity with intestinal contents, I believe that attempts of this kind with hot Dakin's solution, boric acid solution or plain saline, are advisable and once or twice during the day a 1:2000 solution of mercurochrome may be substituted for them. It is possible that a method of this kind may likewise stimulate peristalsis and aid in preventing the much dreaded post-operative ileus, although excessive peristalsis would be objectionable from the standpoint of hindering the localization of infection. In pelvic peritonitis of women irrigation may be more successful and especially if vaginal drainage is provided.

Chemotherapy of Diseases of the Genito-urinary Organs.—Largely owing to the investigations of Young, White and Swartz[170] considerable advances have been made during the past five years in the chemotherapy of bacterial infections of the kidney, urinary bladder and genital organs with mercurochrome, employed first by local application but more recently by intravenous injection as well.

Needless to state, a great many chemical agents have been advocated and employed for the treatment of urethritis, cystitis and pyelitis. For local application, Davis and White[171] and Leonard[172] have enumerated seven qualifications for the ideal urinary antiseptic, believing that mercurochrome and hexy-resorcinol may meet these conditions, as follows:

(1) It should be chemically stable.
(2) It should be non-toxic.
(3) It should be nonirritating to the urinary tract.
(4) It should exert an antiseptic action in high dilution in urine of any reaction.
(5) It should be eliminated in high percentage by the kidney.
(6) It should be eliminated in the urine in sufficient concentration to exert a local antiseptic action and at a rate by which continuous antiseptic action may be attained.
(7) It should be administrable by mouth.

I have already discussed the properties of mercurochrome in Chapter VII but it may be well here to briefly refer to hexy-resorcinol, although the compound has not yet been employed long enough to permit definite statements regarding its chemotherapeutic and practical value as a urinary antiseptic. In 1913 Johnson[173] synthesized the lower homologues of a series of alkyl resorcinols and Rettger, in testing their bactericidal properties, found a rapid increase in the phenol coefficient as the series was ascended. Leonard[114] later discovered that alkylation of resorcinol decreases its toxicity and at the same time increases its bactericidal power in direct proportion to the sum of the atomic weights of the atoms in the side chain. The greatest bactericidal effect is reached in normal hexylresorcinol, which has a phenol coefficient of 46 to 52. The alkyl resorcinols are said to be among the most powerful organic germicides ever described as possessing anything like its degree of nontoxicity to animals and to man.

The clinical cases, although few in number (nine), gave evidence that the drug may be of promise as a urinary disinfectant on account of its strong bactericidal action in either acid or alkaline urine, the rapid and continuous excretion over a considerable period of time following oral administration, and its low toxicity.

Chemotherapy of Infections of the Kidneys.—In the treatment of pyelitis and pyelonephritis due to *B. coli*, *B. lactis äerogenes*, *B. typhosus*, streptococci, staphylococci and other organisms, about the only drugs meriting consideration from the standpoint of chemotherapy are hexamethylamin (urotropin), mercurochrome and hexy-resorcinol. Hexamethylamin unfortunately has not fulfilled original hopes and expectations, because formaldehyd is liberated only in acid urine and, as shown by Stohl and Denning,[175] the concentration must reach at least 1:20,000 to 1:30,000 to be bactericidal. This requires the administration of large doses, but as recently reported by Helmholtz and Milliken,[176] the urine may be kept sufficiently acid (*pH* 5.8 to 7) by the oral administration of either calcium chlorid or ammonium chlorid, while hexamethylamin is given in doses of 1 to 1.5 gm. (15 to 20 grains) four times a day along with large amounts of water. While they never found the formaldehyd content of the urine to reach 1:20,000, yet good results were secured in the treatment of pyelitis of children by this method of administration.

Mercurochrome in 1-per cent. solution has been employed for pelvic lavage in adults with apparently good results, although the staining may interfere with functional kidney tests. According to Young and his associates, it has about the same bactericidal activity as 1-per cent. silver nitrate with the added advantage of being less painful. Of course, pyelitis due to focal infection from the teeth or tonsils may not be cured by lavage alone, but in severe infections the drug may be administered by intravenous injection in dose of about 20 c.c. of 1-per cent. solution per 100 pounds of weight with beneficial results. Great care, however, must be exercised if the kidneys are eliminating poorly with albumin and casts in the urine; under such circumstances the intravenous dose should not exceed 10 c.c. per 100 pounds and in some cases should not be administered by this route at all.

As shown by Young, Scott and Hill,[177] the drug may be given by mouth with little or no gastro-intestinal disturbances, in dose of 0.2 or 0.3 gm. two or three times a day in capsules, as the urine shows colorimetrically a dilution of between 1:15,000 to 1:40,000 which is sufficient for rendering it bacteriostatic. An added advantage may be a reduction in the bacterial flora of the intestine, which may eliminate a urinary infection. But according to Young and Hill,[178] intravenous injections have been particularly efficacious in the treatment of bilateral chronic pyelitis caused by *B. coli* and *B. lactis aërogenes*, in pyonephosis secondary to carcinoma of the bladder, in pyelitis of children, and in retroperitoneal and perinephritic abscesses.

Young and Hill have also reported apparent cures following intravenous injections of gentian-violet and especially in staphylococcus infections, but pelvic lavage with this dye has not been used sufficiently to express an opinion of its value. Davis and Beck[179] found proflavin and acriflavin by oral and intravenous administration apparently efficacious in the treatment of urinary infections due to staphylococci and *B. coli* and especially in the presence of alkaline urine, the dose by mouth being about 0.05 gm. for adults, but Helmholtz and Milliken used this dye by oral administration in dose of 0.01 to 0.025 gm. ($\frac{1}{6}$ to $\frac{1}{4}$ grain) every six to eight hours without benefit in the treatment of three cases of pyelitis of children. Davis[180] has studied the dyes with great care and industry from the standpoint of urinary antisepsis

and of 204 tested found only 28 sufficiently antiseptic to command attention and of these only 13 which were eliminated in bactericidal amounts following the intravenous injection of non-toxic amounts (approximately 0.020 gm. per kilo of weight). Davis and White[181] have also studied the compounds related to phenolsulphonphthalein, but found none possessing antiseptic activity in the urine; chlor-mercury-fluorescein compounds, however, were found to be eliminated by dogs in antiseptic amounts. It is of interest to note in passing that Davis[182] also found that the normal urine of dogs was antiseptic for the bacilli of the colon-typhoid group, but much less so far staphylococci; these observations indicate, therefore, that due care must be exercised in technic and interpretation of results when these animals are employed for experiments on urinary antisepsis.

Leonard has found the oral administration of 0.5 to 1 gm. of hexy-resorcinol in olive oil in capsules three times a day, apparently efficacious in the treatment of a few cases of urinary infections and it would appear that this drug, along with mercurochrome by pelvic lavage, oral or intravenous administration, are the most encouraging and valuable drugs available at present for the chemotherapy of kidney infections. To the best of my knowledge they have not been reported upon in the treatment of tuberculosis of the kidneys and are not likely to be of value in this infection, but in streptococcus, staphylococcus or *B. coli* pyonephritis, it would appear that mercurochrome and hexy-resorcinol are worthy of trial, although great care must be exercised in the intravenous administration of the former. I may state however, that a brief experience with hexy-resorcinol has not so far yielded noteworthy results in kidney and bladder infections; furthermore, some patients cannot take the drug because of nausea and other effects. Hexy-resorcinol is still in the experimental stage at this writing and it is too early to express any definite opinion of its practical value.

Chemotherapy of Cystitis.—In cystitis caused by *B. coli* or a bacillus of this group, streptococci, staphylococci, etc., good results have been secured by the instillation of mercurochrome and especially in *B. coli* infections. It is well to first cleanse the bladder with sterile saline solution and then to inject a freshly prepared 0.5-per cent. solution. Two instillations per day may be given to bring the infection under control as soon as possible and the strength of the solution may be raised to 1-per cent., if well borne, as it usually is, although some patients can scarcely tolerate the 0.5-per cent. solution. The frequency of instillations should be guided by the symptoms and bacteriological examinations of the urine.

Mercurophen in 1:4000 to 1:10,000 solution has likewise proven efficacious by instillation, according to the same plan and is especially useful in the treatment of cases caused by the Gram-positive cocci (staphylococci, streptococci and pneumococci) in which mercurochrome is more likely to fail.

The action of both drugs locally may be enhanced by the oral administration of mercurochrome in dose of 0.2 gm. (3 grains) or hexy-resorcinol in dose of 0.5 gm. (8 grains) three times a day, although the urine must be carefully watched for albumin and casts. Urotropin may likewise prove of some value, provided the urine is kept acid and large doses (1 to 2 gms.) are given three times a day along with large amounts of water.

Chemotherapy of Urethritis and Urethro-prostatitis.—As is well known, a very large number of chemical agents have been advocated for local injection in the treatment of gonococcus infection of the urethra and adnexa of both sexes. The difficulties of chemical disinfection are very great and principally by reason of the fact that efficient bactericides may prove too irritating or fail to reach the gonococci and organisms of secondary infection (staphylo-

cocci, diphtheroid bacilli, *B. coli*, etc.) deeply entrenched in the glands of the urethra and prostate gland. The colloidal and colloidal protein silver preparations and potassium permanganate have long proven favorite disinfectants, Paul,[183] Bruck[184] and others having studied their bactericidal properties very extensively, although, as recently shown by Sollman and Pilcher,[185] the bactericidal activity of these compounds is low and dependent upon the amount of free silver ions immediately available which varies from 7.5 per cent. in the case of protargol to 1.5 per cent. for collargol, 0.4 per cent. for argyrol and to 0.2 per cent. for silvol; they state that these colloidal preparations do not furnish reserve depots for the dissociation of the active ions as commonly believed, and that their value is chiefly soothing and demulcent in addition to what bactericidal action results from the silver ions immediately available. Ballenger and Felder,[186] while observing that a colloidal silver chlorid was highly bactericidal *in vitro*, found that it was of no special value in the treatment of well-established cases of gonorrhea. McDonagh[187] has advocated local injections of colloidal manganese and colloidal palladium; Gladstone[188] has also employed manganese and intramine, and so on through an almost interminable list.

Acriflavin has been widely used for the treatment of gonorrhea in 0.5-per cent. solution and is apparently helpful in many cases. Thus Davis and Harrell[189] found that 1:300,000 solutions were bactericidal for the gonococcus *in vitro* and that local injections were efficacious in the treatment of gonorrhea and capable of penetrating the mucosa of the urethra and bladder; 3 c.c. of 1:1000 solution, 15 to 30 c.c. in posterior cases, were injected twice daily with only slight irritation. The average duration of the disease was believed to have been shortened, but some cases were not benefited. Watson,[190] Armstrong[191] and others have also used the compound by local injection and Wood[192] and Jacob and Verasingan[193] have advised intravenous injections of 150 to 300 c.c. of 1:1000 solutions in the treatment of severe cases of gonococcus infection of the urethra and adnexa, repeating the injections every five days for two or three times if necessary.

Shivers[194] has employed irrigations of mercurophen (1:4000 to 1:10000), preceded by irrigations with 1:8000 potassium permanganate, with uniformly good results.

Mercurochrome has been extensively employed by Young and his associates, by von Lackman and Hagen,[195] Rupel,[196] Whitman[197] and others by intravenous injection with apparently some good results. Lavandera,[198] however, injecting small doses, states that he has found the drug of no value and Brill and Myers[199] have likewise reported that mercurochrome and gentian-violet by intravenous injection did not favorably influence local and systemic gonococcus infections. Redewell and Potter[200] however, state that mercurochrome is excreted in large amounts by the kidneys and also through the prostate, seminal vesicles and other glands of the genito-urinary tract, following intavenous injections of small doses (10 to 15 c.c. of 1 per cent. solutions) every forty-eight hours. A large number of cases of acute gonorrheal urethritis, epididymitis, prostatitis and vesiculitis are stated to have improved rapidly with this medication as well as cases of acute rheumatism, synovitis, myalgia, neuritis and other manifestations of focal infection from primary foci in the prostate and seminal vesicles. To obtain the best results, they advise small enough doses to avoid too early saturation and patients showing mild reactions were observed to respond best to the treatment.

Young, Hill and Scott[201] have recently reviewed reports of four cases of cystitis and prostatitis, one of chancroidal ulcer and twenty-six of urethritis

including some of those referred to above, treated with multiple intravenous injections of mercurochrome, and believe that some cases are benefited by the maximum doses of 4 to 5 mg. per kilogram, but that urethral injections should also be used. For complications like acute gonorrheal arthritis, the results of intravenous injections have been very good; in my opinion intravenous injections of 4 to 5 mg. per kilogram should not be used routinely but employed only in the treatment of exceptionally severe infections.

PART III

CHEMOTHERAPY OF TRYPANOSOMAL DISEASES

CHAPTER IX

PRINCIPLES OF EXPERIMENTAL TRYPANOSOMIASIS IN RELATION TO CHEMOTHERAPY

Historical.—Modern chemotherapeutic investigation may be said to have had its origin in attempts by Laveran and Mesnil[1] in 1902 to develop an efficient treatment for experimental trypanosomiasis of the lower animals. The ease with which trypanosomiasis could be produced in the small laboratory animals and the effects of treatment upon the infection determined, lead these investigators into a closer study of the effects of arsenous acid in mice, rats and dogs infected with *Tr. evansi* (surra) and *Tr. brucei* (nagana). Arsenous acid had been used for many years in the treatment of animals naturally infected with these trypanosomes but with indifferent success. For this reason Laveran and Mesnil undertook this laboratory investigation and also studied the effects of sodium cacodylate, arrhenal, mercuric chlorid, potassium iodid, certain salts of silver, quinin, formol, phenol, chinosal, salicylic acid, chloral, chlorid of lime, toluidin-blue, methylene-blue and a few other substances as well as the serums of human beings and some of the lower animals. The results were negative insofar as concerned the discovery of a superior remedy for experimental trypanosomiasis, but they were nevertheless of great importance by drawing attention to the subject of experimental trypanosomiasis as a means for determining the possible parasiticidal activity of a drug in relation to its toxicity.

In the meantime, Ehrlich had been engaged in his fundamental studies upon the affinity of dyes for cells and first applied these principles for the development of chemotherapy by employing experimental trypanosomiasis. In 1904 Ehrlich and Shiga[2] published their remarkable results with trypan red with which they were able to cure mice infected with *Tr. equinum* (caderas).

In 1903 Ehrlich had studied the effects of atoxyl upon trypanosomes in the test-tube, but the results were negative and apparently the experiments were not considered worth while continuing with experimentally infected animals since the idea prevailed then, as it erroneously does now to some extent, that an agent without parasiticidal activity in the test-tube cannot be expected to prove active in the living animal.

In 1905, however, Thomas[3] found that the injection of atoxyl and particularly mixtures of atoxyl and trypan-red, exerted some degree of curative activity in monkeys, dogs, kittens, rabbits, guinea-pigs, rats and mice experimentally infected with different species of trypanosomes (*Tr. gambiensi, Tr. brucei, Tr. equiperdum, Tr. evansi, Tr. equinum* and *Tr. dimorphon*). Sodium arsenate was found without trypanocidal activity. This work attracted the attention of Ehrlich and especially the results observed with atoxyl in *Tr. gambiensi* infections. As a result Ehrlich and Bertheim re-studied the chemistry of this remarkable substance, finding that it was not a chemically indifferent meta-arsinic-acid-anilid but an amino-derivative of phenylarsinic acid and a substance opening up wide

possibilities for the synthetic production of different combinations possessing lower toxicity and higher trypanocidal activity. At about the same time Ehrlich and Shiga (1904) studied the influence of certain dye compounds in experimental trypanosomiasis, followed in 1906 by the extensive investigations of Nicolle and Mesnil[4] with dyes of the benzidine group. These investigations and especially the work with atoxyl eventually led to the discovery of dioxydiaminoarsenobenzol (salvarsan) by Ehrlich, Bertheim and Hata, the greatest triumph in the science of chemotherapy at the present time. Atoxyl, therefore, and its humble discoverer Béchamp, are to be given the place of first importance in the history of chemotherapeutic science, and to Laveran and Mesnil belongs the credit of discovering the application of experimental trypanosomiasis for the conduct of chemotherapeutic researches.

Experimental Trypanosome Infections Commonly Employed in Chemotherapeutic Investigations.—Fortunately for the conduct of chemotherapeutic investigations, many of the trypanosomes causing disease among human beings and the lower animals are capable of infecting the smaller laboratory animals as mice, rats, guinea-pigs and rabbits. As a general rule mice have been preferred by German and French investigators and mice and rats by English and American investigators. Guinea-pigs, rabbits, and to a lesser extent dogs, goats and donkeys, have also been employed largely to supplement the tests conducted with the smaller animals.

The ability of many of these trypanosomes to infect the smaller laboratory animals has aided the development of chemotherapy in an immeasurable degree and especially in studies with the dyes and arsenicals, because these animals may be used in large numbers by reason of their cheapness and ease of handling.

As previously stated, mice and rats have been mostly employed not only by reason of their cheapness and ease of handling, but because in them trypanosomiasis is essentially an acute blood infection, a *trypanosomia*, ending fatally. It is easy to study the influence of a medicament upon the course of the disease and the results are secured in a comparatively short time. In guinea-pigs and rabbits, however, experimental trypanosomiasis is a more chronic infection of the fixed tissues; this is likewise very fortunate for experimental chemotherapy, as it permits the study of compounds under conditions more closely duplicating the course of trypanosomiasis in natural infections of man and the lower animals.

Non-pathogenic trypanosomes have proven unsuitable for chemotherapeutic investigation. Their appearance in the peripheral blood is usually intermittent and the absence of lesions and their non-fatal character leave little that is definite for the purposes of experimental chemotherapy. Furthermore some of them, and notably *Tr. lewisi*, are more resistant to trypanocidal agents than pathogenic trypanosomes. *Therefore the choice of trypanosomes for chemotherapeutic investigation is of importance* and to be carefully considered. But before discussing more fully this subject of choice of animals and organisms for chemotherapeutic investigation, it may be well to first consider certain general factors and the symptoms and lesions of trypanosomiasis produced experimentally in the smaller animals.

Natural and Acquired Virulence of Trypanosomes in Relation to Experimental Trypanosomiasis.—Extremely severe and rapidly fatal trypanosome infections are undesirable in experimental chemotherapy because slight trypanocidal effects on the part of the drug under study may become masked and readily overlooked. As a general rule, infections with a highly virulent strain of a given species of trypanosome are more difficult to influence with trypanocidal compounds than less virulent strains and for this reason the same compound tested in different laboratories, by the same method and employing the same species of organism, may yield different results.

Influence of Natural Virulence.—In the first place the period of incubation or interval of time elapsing between the inoculation and first appearance of trypanosomes in the blood or production of symptoms and the duration of life of the animal varies considerably according to the natural virulence of the various pathogenic trypanosomes. For example, *Tr. brucei* is usually more virulent for the common laboratory animals than *Tr. equiperdum*, *Tr. dimorphon*, *Tr. equinum* and *Tr. congolense* and between these extremes in varying degree are *Tr. gambiensi*, *Tr. evansi* and *Tr. rhodesiense*. The lesions and symptoms produced by the different trypanosomes in any one species of animal are remarkably similar, but the rapidity of their development and influence upon the duration of life vary in some degree, according to the species of trypanosome.

The Influence of Animal Passage upon Virulence.—Probably of even greater practical importance in relation to chemotherapeutic investigations are the changes in virulence that may be acquired by any given strain of pathogenic trypanosome, as by its "direct" passage from rat to rat or by "crossed" passage in different kinds of animals as well as by its rate of passage. Thus Thomas and Breinl,[6] working with *Tr. gambiense*, found that "if a strain is repeatedly and quickly run through animals of the same species, it will acquire a certain virulency for such a species, but this continues only so long as the strain is not run through other species of animals." However, according to Laveran,[7] passage through *guinea-pigs* does not increase the virulence of all strains; for example, in his experiments the virulence of *Tr. evansi* and *Tr. gambiense* was increased following a series of passages while the virulence *Tr. brucei* was reduced and *Tr. congolense* remained unchanged. According to other investigators, the virulence of a strain by continued direct passage may be increased for some animals and diminished for others; Martini[8] states that a strain of *Tr. brucei* run through rats and mice acquired a virulence not only for these animals but for dogs as well, whereas when passed through guinea-pigs and rabbits it became only slightly more virulent for rats, mice and dogs. I have found in my experiments that the virulence of *Tr. equiperdum* was increased by rapid passage through a series of rats but that the strain did not acquire an enhanced virulence for guinea pigs and rabbits; on the contrary passage of *Tr. equiperdum* through guinea pigs or rabbits usually reduced its virulence for rats and mice to a slight degree. Lavaran and Mesnil[9] also report that a strain of *Tr. equiperdum* which at first killed mice regularly in 5 to 10 days almost lost entirely its virulence after being kept in stock guinea-pigs for 2 to 3 months. Voegtlin, Dyer and Miller[9a] have recently reported that the virulence of a strain of *Tr. equiperdum* for rats was reduced by transfer through rabbits and a dog; curiously and probably of more importance, passage of an arsenic resistant strain through these animals resulted in a sharp reduction of this property, a subject which I will discuss with more detail in Chapter XII.

The *rate of passage* of a given strain is of considerable importance since the rapid transfer from animal to animal tends to increase the virulence. For this reason transfers at short intervals for propogating a strain should be avoided.

The *vitality of the trypanosomes and stage of the infection of the stock animal* at the time blood is drawn for transmission of the trypanosomes, also influence the character and termination of any particular infection in a given animal. The blood used for inoculation should be taken from a live or freshly killed animal and not from a dead animal since trypanosomes soon lose their infective power after the death of the host. Furthermore, blood should not be taken just before the death of the stock animal since at this time many trypanosomes may show degenerative changes and loss of motility. Moreover, as stated by Pearce and Brown, "toward the terminal stages of an infection, there are present in the blood certain 'immune substances,' the nature and amount of which are as yet little understood."

Influence of Variations in Virulence of Trypanosomes upon the Chemotherapy of Experimental Trypanosomiasis. The Arsphenamin Coefficient. During the course of trypanocidal experiments frequently conducted over a period of time as in the routine testing of the trypanocidal activity of arsphenamin and neoarsphenamin, the strain of trypanosomes (usually *Tr. equiperdum*) is apt to vary at times in resistance to these trypanocidal agents. Naturally when the resistance is markedly increased one first thinks of the possibility of acquired "fastness" through the error of employing a strain passed through animals injected with these arsenical compounds. In my experience, however, the strain may acquire a sufficient degree of enhanced virulence by passage through rats at short intervals to influence the results of trypanocidal tests. Under these circumstances the untreated controls may die one or two days earlier than usual or expected and thereby indicate that enhanced virulence may be responsible for an apparent decrease

in trypanocidal activity of the drug. On the other hand, passage of such a strain through a guinea-pig generally reduces its virulence again for rats. At any rate the trypanosomes are subject to changes in resistance that are not to be ascribed to "drug fastness" and for this reason, I have always included in each set of trypanocidal tests a lot of arsphenamin carried along in vacuum tubes from month to month. Arsphenamin does not change in trypanocidal activity when properly preserved, and serves as a control or "coefficient" for comparing the trypanocidal activity of different lots of arsphenamin, neoarsphenamin or other compounds. I shall refer to this subject of "*arsphenamin coefficient*" in the next chapter and discuss in more detail its advantages for trypanocidal tests. The adoption of this means for expressing trypanocidal values will go far toward the standardization of trypanocidal tests and give a means for comparison in different laboratories analogous to the "phenol coefficient" in bactericidal tests and the use of standard toxin or antitoxin for the titration of diphtheria and tetanus antitoxins.

The Influence of "Drug Fastness" upon the Chemotherapy of Experimental Trypanosomiasis.—Of more importance than variations in virulence of trypanosomes in relation to experimental chemotherapy is the possibility of acquired "drug-fastness." Trypanosomes readily acquire "fastness" to arsenical compounds and in laboratories conducting trypanocidal tests routinely there is always this danger unless proper precautions are taken. Trypanosomes taken from rats receiving insufficient amounts of arsphenamin or neoarsphenamin for sterilization, are usually more resistant to these compounds than a normal strain and several transfers of this kind usually results in imparting to the strain a well marked degree of resistance to the effects of arsphenamin and neoarsphenamin. For this reason animals employed for the propogation of the trypanosomes should be kept in an isolated place and removed from the possibility of becoming "fast" to the class of compounds being studied.

Variation in Natural Resistance of Trypanosomes to Therapeutic Agents. Of great importance in relation to the chemotherapy of experimental trypanosomiasis is the well known fact that some trypanosomes are more resistant to trypanocidal agents than others. For this reason an agent possessing high trypanocidal activity for one strain of trypanosome cannot be assumed to possess an equal degree of activity for other pathogenic organisms. Even different strains of the same species of trypanosome may show variations in resistance to the same trypanocidal agent, but these are not as marked as shown by different species, and sometimes are to be ascribed to variations in virulence rather than specific resistance to the therapeutic agent.

In his early experiments on the chemotherapy of experimental trypanosomiasis Ehrlich found that trypan-red was less active against *Tr. brucei* than against *Tr. equinum* in mouse infections. Laveran found that arsenic trisulfid was more active against *Tr. congolense* than against *Tr. dimorphon* in guinea-pigs. Atoxyl was found by Mesnil, Nicolle and Aubert, active against *Tr. gambiense* but only feebly for *Tr. dimorphon* and totally inactive against *Tr. congolense.* Monfort found arsenophenylglycin active in the treatment of *Tr. gambiense* from the point of view of relapses in mice, while *Tr. rhodesiense* and *Tr. dimorphon* infections were slightly more resistant and *Tr. congolense* very resistant. Mesnil and Brimont,[10] working with tartar emetic and infected mice, found *Tr. evansi* and *Tr. equiperdum* more susceptible than *Tr. brucei, Tr. equinum, Tr. gambiense* and *Tr. dimorphon* infections. More recently Yakimoff and Wassilevsky[11] found, in working with *Tr. equiperdum* infections in mice, that the ratio of the curative to the tolerated dose of luargol was 1:3 while Danysz found the ratio 1:80 in mice infected with *Tr. evansi* and 1:100 with *Tr. gambiensi.* Pearce and Brown report that in their work, *Tr. equinum* was found least resistant and that *Tr. gambiensi, Tr. brucei, Tr. evansi,* and *Tr. equiperdum* followed in the order named.

I have repeatedly found that in rats arsphenamin, neoarsphenamin and other new arsenical compounds were more active against *Tr. equinum* and *Tr. equiperdum* than against *Tr. brucei;* the results of an experiment shown in the following table brings out the variations in resistance of these three pathogenic trypanosomes. In these experiments white rats weighing from 250 to 300 grams were employed and all animals were infected in a uniform manner by the intraperitoneal injection of approximately 500,000 of the different trypanosomes, the drugs being administered by intravenous injection twenty-four hours later:

Variation in Resistance of Different Trypanosomes to Arsphenamin and Neoarsphenamin

Substance	Trypanocidal Dose per Kilo Weight			
	For Tr. Equinum	For Tr. Equiperdum	For Tr. Brucei	For Tr. Lewisi
Arsphenamin.....	0.001–0.002	0.002–0.004	0.006–0.010	more than 0.040
Neoarsphenamin.....	0.0015–0.005	0.003–0.008	0.012–0.016	more than 0.040

Apparently the variation in resistance of different trypanosomes to specific therapeutic agents is due to inherent resistance of the organisms but as will be shortly discussed, variations in resistance may be due in part at least to differences in virulence. Furthermore, as wisely pointed out by Pearce and Brown, the possibility of drug fastness should be remembered. Since so much experimental work has been done with the various laboratory strains of trypanosomes and since it is a comparatively easy matter to render a strain arsenic fast as I know from experience, it is not always possible to say whether the resistance offered to trypanocidal agents, and especially arsenic compounds, is natural resistance or one which has resulted from acquired drug fastness.

Numeric Relationship of Infection to Experimental Trypanosomiasis and Chemotherapy.—While it is necessary to use a parasite of sufficient virulence, aggressiveness and vitality to yield definite results in experimental chemotherapy, yet it is possible, as shown by the writer,[12] to mask the finer grades of therapeutic effects by an overwhelming infection, or, on the other hand, lose or vitiate an experiment by infecting with too few parasites. The time of true primary incubation, that is, the interval elapsing between inoculation and the appearance of trypanosomes in the blood, as well as to some extent the duration of the lives of the animals, are factors influenced by the numbers of trypanosomes injected. Of greater importance, as will be shortly discussed, is the fact that the parasitropic effects of a drug or substance under study and the resistance of the animal to the drugs organotropic effects are apparently modified, to some extent at least, by whether the animal (rat) is infected with small or large numbers of trypanosomes.

Because of the importance of this factor of numbers of trypanosomes injected into rats in relation to chemotherapeutic results, I have worked out a method for counting trypanosomes and inoculating with approximately known numbers, the technic being described in the succeeding chapter.

In general terms it may be stated, therefore, that the duration of primary incubation and accordingly the duration of life in experimental trypanosomiasis are influenced by the number of trypanosomes inoculated. Large differences in numbers exert these influences, small differences do not. After trypanosomes have appeared in the blood, the duration of life is about the same regardless of the numbers of organisms injected. But the numbers of trypanosomes inoculated into rats has likewise an important bearing upon the results of trypanocidal tests with various medicaments. This is especially true if the trypanocidal agent is given at an arbitrary interval after inoculation, as in the technic of my trypanocidal test in which the compound under study is administered twenty-four hours after trypanosomes have

been injected intraperitoneally. If large numbers of trypanosomes are injected a few organisms may be found next day in the blood and the amount of trypanocidal substance required for sterilization is greater than when rats are injected with small numbers of trypanosomes, as shown by Schamberg, Raiziss and myself[13] and of which the following table is an example:

THE NUMERICAL RELATIONSHIP OF INFECTION OF RATS WITH TR. EQUIPERDUM TO TRYPANOCIDAL ACTIVITY

Rat No.	Weight in Grams	Approximate Infection (Intraperitoneal)	Arsphpen. per Kilo	Examination of Blood								
				1 Da.	2 Da.	3 Da.	4 Da.	5 Da.	6 Da.	7 Da.	8 Da.	9 Da.
1	110	1,000	0.002	−	−	−	−	−	−	−	−	−
2	105	10,000	0.002	−	−	−	−	−	−	−	−	−
3	120	100,000	0.002	−	−	−	−	+	++	++++	++++	D
4	120	500,000	0.002	−	−	−	+	++	++++	D		
5	105	1,000,000	0.002	−	−	+	++	++++	++++	D		
6	115	10,000,000	0.002	−	+	++	++++	D				
7	100	100,000,000	0.002	−	+	++	++++	++++	D			

In trypanocidal tests conducted according to the Voegtlin method the influence of numerical infection upon trypanocidal values is not as important as in my method, because in the former the medicament is not administered until trypanosomes have appeared in the blood (about 100,000 to 200,000 per c. mm.). The intraperitoneal inoculation of rats with large numbers of trypanosomes simply means, therefore, that the medicament must be given earlier than when smaller numbers of trypanosomes are inoculated, since treatment is not begun in this method until examination of the blood shows the presence of the number of trypanosomes mentioned above.

Relation of Age and Weight of the Experimental Animal to the Chemotherapy of Trypanosomiasis.—In a general way young animals are more susceptible to infection with trypanosomes than older and heavier animals. This is especially true of rats, guinea pigs and rabbits. After animals are half to three quarters grown, the resistance to infection becomes more uniform, whereas in very young and old heavy animals the degree of natural resistance varies in sufficient degree to constitute a factor of variation in experimental chemotherapy.

Relation of the Route of Infection to the Chemotherapy of Experimental Trypanosomiasis.—Investigators in experimental trypanosomiasis have employed different routes of inoculation of animals. The majority have infected mice subcutaneously and intraperitoneally, rats and guinea-pigs intraperitoneally and rabbits intravenously.

The choice of route of inoculation, however, is not one of indifference although it may be influenced by convenience and technical difficulties. Infection by subcutaneous and intramuscular injection is generally followed by one or two days longer period of incubation than by intraperitoneal and intravenous injection and the animals consequently live somewhat longer. In experimental chemotherapy the administration of a medicament twenty-four hours after subcutaneous infection shows a greater influence upon the trypanosome infection than after intraperitoneal inoculation. The differences are mainly due to the fact that trypanosomes apparently do not proliferate in the subcutaneous tissues and invade the blood stream as rapidly as when inoculated intraperitoneally; consequently, fewer require destruction when a trypanocidal substance is administered twenty-four hours later.

Relation of the Route of Administration of Drug to the Chemotherapy of Experimental Trypanosomiasis.—As would be expected experiments have shown that the route of administration of a trypanocidal agent has an influence upon its trypanocidal activity, that is, upon the amount required for effecting complete sterilization. Very probably this is largely a question of rate of absorption and elimination of the medicament.

With subcutaneous injection the amounts of arsphenamin and neoarphenamin for example, required for the sterilization of rats inoculated intraperitoneally twenty-four hours previously, is usually higher than when the drugs are given intraperitoneally or intravenously; sulpharsphenamin however, may be more trypanocidal by subcutaneous or intramuscular than by intravenous injection.

With virulent trypanosome infections, as mice or rats infected intraperitoneally with large numbers of *Tr. brucei*, the subcutaneous injection of a medicament may be apparently without influence upon the infection even though the medicament is known to possess some degree of trypanocidal activity. This is due to the fact that the trypanosomes, and especially if they have been inoculated 24 hours previously, have gained too much headway in view of the slower absorption of the medicament from the subcutaneous tissues. Not infrequently when mice are employed, the medicaments are given by subcutaneous injection and in the presence of a virulent infection, there is danger that slight degrees of trypanocidal activity may be masked and hidden.

Compounds administered intraperitoneally, however, may prove trypanocidal in the same or but slightly larger doses than required by intravenous injection. This is very fortunate as it simplifies the technic in testing some compounds, but care must be exercised in the choice of compounds administered by this route as some produce so much local irritation as to kill the animal with peritonitis.

Finally it would appear proper always to give the medicament in experimental infections according to the route by which it is proposed to give it in the treatment of disease of human beings. For example, arsphenamin and neoarsphenamin employed in the treatment of syphilis are generally given intravenously and especially in the treatment of acute syphilis in the primary and secondary stages of the disease. If the compounds are injected intravenously in the experimental study of their influence upon trypanosomiasis and rabbit syphilis, they are subject to the same possible modifications in the blood stream as occurs when they are administered to human beings and this is in conformity with what should be a rule in experimental chemotherapy namely, to study the medicament under conditions approaching as nearly as possible the actual disease in human beings or the lower animals for which an efficient chemotherapy is being sought.

Time of Administration of Trypanocidal Agent in Relation to the Chemotherapy of Experimental Trypanosomiasis.—In acute trypanosomiasis of mice and rats, the results of trypanocidal tests are greatly influenced by the duration of the infection at the time the medicament is administered. This is of course to be expected inasmuch as the destruction of large numbers of trypanosomes requires more medicament than small numbers, regardless of what opinions we may entertain regarding the mechanism of trypanocidal activity.

The results are also influenced by the rapidity with which the medicament is absorbed and eliminated. For example, if a trypanocidal agent as arsphenamin or neoarsphenamin is administered intravenously to rats immediately or within a few hours after intraperitoneal inoculation of *Tr. equiperdum*, one

would expect the maximum effects but experiment has shown that this is not the case. Apparently the drug is rendered inert or eliminated too rapidly for complete sterilization when given in small amounts and is less effective against trypanosomes in the peritoneal cavity than in the blood.

In experimental chemotherapy the subject is of particular importance because if uniform results are desirable, the method must provide for the treatment of approximately equal infections from time to time. Furthermore, if the compound under study possesses but feeble trypanocidal activity, the effects may be elicited much more readily by administering the compound during light infections than by waiting until the organisms have greatly multiplied in the blood. In my experiments it was noted that when the medicaments were given within four hours of infection that sometimes more were required for sterilization than after a 24 hour period. After 48 hours however, larger and larger doses were required as the number of trypanosomes in the blood progressively increased. On the last day or two of life when the number of trypanosomes in the blood may exceed the number of erythrocytes, it is difficult to save the animal even with comparatively enormous doses of arsphenamin or neoarsphenamin.

Symptoms and Lesions of Experimental Trypanosomiasis in Mice and Rats.—Infection of mice and rats with pathogenic trypanosomes is generally an acute, progressive disease characterized by the constant presence of parasites in the peripheral blood and ending fatally. The duration of primary incubation, the interval between the inoculation and first appearance of organisms in the peripheral blood, varies with the species and virulence of the trypanosomes, the number inoculated and the route of inoculation.

As a general rule trypanosomes are to be found in the blood in from twenty-four to forty-eight hours after intraperitoneal injection (the usual route of inoculation) and from then on multiplication is rapid until death, when they seem to be more numerous than the red corpuscles. Occasionally the course of *Tr. equiperdum* infections is interrupted for a day or two by a slight remission in the number of organisms in the blood. *Tr. equinum* infection may also run a relapsing course, especially in mice, the parasites being greatly diminished in number on the fourth or fifth day followed by rapid increase and death on the tenth to fourteenth day after inoculation.

The animals are remarkably free of symptoms up to the time of death. During the last few hours they are apt to be quiet and drowsy followed by the development of tremors, violent convulsions and death. On the other hand, death may follow in a state of coma without convulsions. Laveran and Mesnil have stated that mice infected with surra, caderas and dourine become very quiet and sit huddled up with a rough and bristling coat, eyes closed, and insensitive to external stimuli; just before death the corneas may become white and opaque.

Symptoms and Lesions of Trypanosomiasis in Guinea Pigs and Rabbits.—Experimental trypanosomiasis in guinea-pigs and rabbits constitutes a type of infection in sharp contrast to trypanosomiasis in the mouse and rat. Instead of an acute and rapidly fatal blood infection, the parasites appear in the blood only at intervals and chronic or subacute involvement of the fixed tissues becomes a more conspicuous and predominating feature. Pearce and Brown have given an excellent description of the disease in these animals.

The Application and Utilization of Experimental Trypanosomiasis in the Development of Chemotherapy.—Experimental trypanosome infections of the lower animals have proved of great value in the study of the principles of chemotherapy, that is, the selective action of chemical substances for microparasites in living hosts. The large size of these organisms, the ease by which laboratory animals may be infected and the course of the infection studied, the fatal character of the infection with pathogenic trypanosomes and the cheapness of mice and rats, have been some of the reasons why experimental trypanosome infections have commanded so much attention and

investigation. Experimental chemotherapy is usually a very expensive type of investigation; large numbers of animals are required and the time and labor involved are tremendous.

Choice of Animal.—As previously mentioned trypanosomiasis in mice and rats is an acute blood infection without much involvement of the fixed tissues. Trypanosomiasis of guinea-pigs and rabbits is largely one of infection of the fixed tissues in which the blood is invaded only at intermittent periods. In mice and rats, the disease is usually rapidly fatal and the problem of treatment analogous to acute bacterial infections with bacteremia; in guinea-pigs and rabbits the diseases is chronic and may run months and even years.

For determining *quickly* the trypanocidal effect of a drug, mouse and rat infections are to be preferred but the information yielded may not have a direct application in the treatment of trypanosomiasis in human beings, horses and cattle. In the latter the question of tissue involvement is more important than blood invasion and compounds like arsphenamin and neoarsphenamin, possessing extremely high trypanocidal activity in mouse and rat infections, have less effect in guinea-pig and rabbit infections and a great deal less in the treatment of trypanosomiasis of human beings, horses and cattle. Mouse and rat tests are splendid for preliminary orientation—for learning quickly whether or not a compound under study possesses trypanocidal activity, but for securing data on its probable value in the treatment of human trypanosomiasis and natural infections of horses, cattle and other of the larger animals, tests on guinea-pigs and rabbits are required in order to study the drug in the presence of chronic tissue infections where passage of the drug into the pathological lesions and healing of the latter are questions of prime importance.

As between the choice of mice or rats for the acute blood infections, I think preference should be given the albino rat of 100 to 200 grams of weight. Breinl and Nierenstein[14] state that their reaction is more constant than mice, likewise their resistance to infection. They are very susceptible to trypanosome infections, are cheap and easy to handle (with gloves). Furthermore, in my experience, it is easier to inject them intravenously and intravenous injections are generally employed in experimental chemotherapy. On the other hand, Dale and White[15] have preferred mice for conducting the official toxicity and trypanocidal tests of arsphenamin and neoarsphenamin in England; their associates Burn, Durham and Marchal found that the results were practically the same as observed with rats, that mice were easier to handle and may be injected intravenously with less time and labor.

As between guinea-pigs and rabbits for chronic tissue infections, I believe that preference should be given rabbits of about 1500 to 2000 grams, and preferably male animals. They may be infected by either intravenous or intraperitoneal injection and repeated intravenous injections of medicament are given with great ease. Furthermore, it is easier to examine the blood repeatedly and the tissue changes are more definite and detectable.

Choice of Parasite.—The majority of chemotherapeutic investigations in experimental trypanosomiasis have been conducted with *Tr. brucei.* Infections with this parasite and *Tr. evansi* are usually highly virulent, and rapidly invasive. *Tr. equiperdum, Tr. gambilnsi* and *Tr. equinum* are less virulent and less rapidly fatal.

For general chemotherapeutic work I prefer *Tr. equiperdum* infections in rats and *Tr. brucei* infections in rabbits. *Tr. brucei* infections of rats are usually too virulent and rapidly fatal with the likelihood of masking the feeble but definite trypanocidal effects of some drugs. On the other hand, in rabbits *Tr. brucei* infections are better than *Tr. equiperdum* infections because the symptoms and lesions are usually more marked.

For specific chemotherapy of a certain infection, the trypanosome of that disease should be employed in the final experiments and the laboratory animal should be one in which the trypanosome produces lesions approaching in character those actually produced in the natural disease. For example, in work upon the chemotherapy of human sleeping sickness, *Tr. gambiensi* should be used in rabbits for the final tests of a drug; in dourine of horses, *Tr. equiperdum* infections in rabbits should be used. In other words, our final efforts should be made under conditions approaching the actual or natural disease as closely as possible—using rabbits infected with the specific organ-

ism in order that the particular parasite may be attacked in the chronic tissue lesions, in the spinal fluid and as they occur intermittently in the blood.

Application of Experimental Trypanosomiasis in the Chemotherapy of Syphilis and Other Spirillar Infections.—Investigations in the chemotherapy of experimental trypanosomiasis have had their greatest *practical* value and application in the development of the treatment of syphilis. Ordinarily it may be said that a chemical compound possessing a high and specific parasitropism for trypanosomes may not possess a similar destructive affinity for such organisms as *Spirochaeta pallida*, *Spirillum obermeieri* and other pathogenic spirilla. Indeed, opinion has leaned toward the assumption that no reliable comparison could be drawn between the trypanocidal effects of a drug in rats or mice and spirocheticidal effects in human beings or rabbits.

Many of the organic arsenical compounds, however, and especially arsphenamin and neoarsphenamin, have proved both trypanocidal and spirocheticidal. This fact has greatly aided in testing the curative activity of arsphenamin and neoarsphenamin because there is a close parallelism between trypanocidal and spirocheticidal activities insofar as the organic arsenicals are concerned. For example, I have determined the smallest trypanocidal dose of several different brands of arsphenamin and neoarsphenamin according to my method described in the succeeding chapter. Rabbits were infected intratesticularly with *Spirochaeta pallida* and treated with varying amounts of the different arsphenamins and neoarsphenamins by intravenous injection as soon as the testicle presented the lesion of syphilis and numerous spirochetes when examined microscopically. With rabbits it was determined for each lot of arsphenamin and neoarsphenamin the minimal amount required to not only cause the disappearance of all organisms from the testicular lesions but likewise from the neighboring lymph glands, which were emulsified and injected into fresh animals. The results of my experiments have shown that arsphenamin was trypanocidal in 3 to 4 mgm. per kilogram of rat and spirocheticidal in 8 to 12 mgm. per kilogram of rabbit. In general there was parallelism between the two values. For example, an arsphenamin trypanocidal in dose of 4 mgm. per kilogram was spirocheticidal in 8 mgm.; a second arsphenamin was trypanocidal in 6 mgm. and spirocheticidal in 12 mgm.; a third arsphenamin was trypanocidal in 3 mgm. and spirocheticidal in 10 mgm. For arsphenamin therefore, the relation was quite constant, the trypanocidal dose being about one half the spirocheticidal dose, that is, the relation being 1:2 to 1:3.3.

With neoarsphenamin the relation between trypanocidal and spirocheticidal was less constant, the trypanocidal dose being from 1.3 to 6 times less than the spirocheticidal dose. For example, one lot was trypanocidal in dose of 6 mgm. per kilogram and spirocheticidal in 8 mgm.; another lot was trypanocidal in dose of 2 mgm. and spirocheticidal in 12 mgm. etc.

Clinical evidence of a parallelism between trypanocidal and spirocheticidal activities of arsphenamin and neoarsphenamin has been furnished by the investigations of Mills and White,[16] who determined the minimal trypanocidal dose of a number of compounds of British manufacture employing white mice infected with *Tr. equiperdum*. Compounds showing different trypanocidal activities were then selected and administered in dose of 0.45 gm. by intravenous injection to human beings with syphilis, care being taken to select primary cases with chancres most nearly approaching a clinical uniformity in order to minimize error due to varying degree of rate and amount of penetration of the drug into the lesions. The lesions were then examined for spirochetes 18–20 hours later and these investigators concluded that the correspondence between the two values was so good as to justify the conclu-

sion that the determination of the therapeutic action on mice infected with trypanosomes is a very valuable index, if not an accurately quantitative measure, of the therapeutic activity of different samples of neoarsphenamin for syphilis in man. The method has, accordingly been put into routine use in the Medical Research Council's Department of Biological Standards in England, an occasional check of therapeutic activity being thus imposed, in addition to the regular testing of every batch of such products for absence of undue toxicity.

It cannot be said, however, that all organic arsenical compounds possessing trypanocidal activity have an equal degree of spirocheticidal power; for example, tryparsamid, the sodium salt of N-phenylglycineamide-p-arsonic acid, prepared by Jacobs and Heidelberger[17] and tested biologically by Brown and Pearce, possesses a very high curative activity against many different pathogenic trypanosomes but much less effect upon *Spirochaeta pallida* and especially in the treatment of human syphilis.

In a general way, however, the majority of organic arsenical compounds and some dye substances have shown both trypanocidal and spirillocidal activities. Most of them have proven more highly spirillocidal than trypanocidal insofar as tests employing *Sp. gallinarum* (fowl spirillosis) and *Sp. obermeieri* (relapsing fever) are concerned. Most of Ehrlich and Hata's early work was done with these spirilla. Some compounds possessing feeble trypanocidal activity were found actively spirillocidal indicating that fowl spirillosis and mice infected with *Sp. obermeieri* are more easily cured than mice or rats infected with trypanosomes.

Since trypanosomes may be more resistant to destruction by chemical agents than spirilla, a compound unable to influence a trypanosome infection may yet demonstrate curative activity for spirillar infections like *Sp. obermeieri* infections of mice, *Sp. gallinarum* infections of fowls or *Spirocheta pallida* infections of rabbits. Therefore, *trypanocidal tests may be said to possess a greater positive than negative value and especially in the experimental chemotherapy of spirillar diseases*; that is to say, a drug without demonstrable trypanocidal activity may still prove spirocheticidal. In this connection special mention should be made of mercurial compounds. Even in amounts equivalent to their maximum tolerated doses they are without or almost without demonstrable trypanocidal effect and yet the experience of centuries has demonstrated their curative activity in the treatment of human syphilis.

CHAPTER X

TECHNIC OF TRYPANOCIDAL TESTS

As discussed in the preceding chapter there are many biological and technical factors to be considered in conducting trypanocidal tests. The choice of animal and infecting trypanosome, the method of inoculation, the time interval between infection and administration of the compound under study and the route of injection of the latter, are the more important of these biological and technical factors. The simple infection of a series of rats or mice with a pathogenic trypanosome followed by administration of the compound and a subsequent study of its effects if any upon the infection, are relatively simple technical procedures, unless a maximum degree of accuracy and uniformity of results are required, in which case technical details require the closest attention.

Requirements of an Acceptable Trypanocidal Test.—In the majority of instances trypanocidal tests are required for the purpose of determining whether or not a chemical substance possesses trypanocidal activity; and if so, a quantitative measure of this property. Tests of this kind are being routinely employed at present in this country and England for testing the curative activity of arsphenamin, neoarsphenamin and allied compounds, since, as stated in the preceding chapter, a measure of this property is acceptable as an index of spirocheticidal activity insofar as these arsenical compounds are concerned. Rat and mouse infections are employed in order that the results may be obtained as quickly as is consistent with accuracy and with the minimum expense and labor. When it is desired to study compounds for the treatment of human trypanosomiasis or trypanosomiasis of the lower animals (particularly horses and cattle), experimental guinea pig or rabbit infections are advisable in addition to rat or mouse tests, in order that the medicament may be tested for curative activity in the presence of chronic tissue infections. These guinea pig and rabbit tests are also advisable in studies with compounds to be used in the treatment of syphilis, because the analogy between rat trypanosomiasis and human syphilis holds good only for the early stages of syphilis, when spirochetes are present in the blood and lymph and before marked tissue changes have occurred; whereas the tissue changes of chronic and latent syphilis bear a closer analogy to the pathological tissue changes in human trypanosomiasis and to experimental trypanosomiasis of guinea-pigs and rabbits. It may be said in this regard that the chemotherapy of acute primary syphilis has been solved with arsphenamin and neoarsphenamin; that the results are almost as satisfactory as the treatment of trypanosomiasis of rats and mice, but this does not apply to the treatment of cases of long standing chronic syphilis with tissue changes. For the development of a more satisfactory chemotherapy of syphilis in its latent and tertiary stages, guinea-pig and rabbit trypanocidal tests and treatment of rabbit syphilis are probably just as important as rat or mouse trypanocidal tests.

The requirements of an acceptable trypanocidal test may be summarized as follows:

1. *It should yield quantitative results in an accurate and consistent manner* so that the measure of trypanocidal activity may be expressed in milligrams of compound per gram of body weight of animal.

2. *The same compound tested at different times should yield the same or approximately the same results, providing it is known that chemical changes in the compound likely to alter trypanocidal activity have not occurred.* Since arsphenamin is known to maintain its activity in a uniform manner over long periods of time I have checked up my technic routinely with this substance and for several years have compared the trypanocidal activity of other substances with arsphenamin in what has been designated as the "arsphenamin coefficient."

3. *It should be as economical as possible in both animals and labor.* Chemotherapeutic research is expensive—probably the most expensive of all medical research. Ordinarily many experiments requiring large numbers of animals and much time and labor are required for the thorough study of any compound. For routine tests to pick out the "leads" or more promising compounds, the test should be economical and yield reliable information as quickly as possible. Elaborate and time consuming tests are uncalled for and unnecessary. The simpler the technic the better are the results, providing fundamental principles are observed. For routine tests rat and mouse infections are satisfactory when conducted with a pathogenic organism as *Tr. equiperdum* or *Tr. brucei;* for special tests involving the question of treatment of chronic tissue lesions, guinea pig or rabbit tests are demanded. Likewise trypanocidal tests for the development of the chemotherapy of a special trypanosome disease should employ if possible the organism of that particular infection, as *Tr. gambiensi* in chemotherapeutic investigations or African sleeping sickness.

Propagation of Trypanosomes.—Pathogenic trypanosomes are propagated by injecting blood from an infected animal into stock animals at suitable intervals. *Due care must be exercised against inoculating too many trypanosomes at too close intervals, because this practice sometimes results in greatly enhancing the virulence of the organisms.*

As a general rule, trypanosomes should be propagated in both rats and guinea-pigs, the former for trypanocidal tests employing rats and the latter for tests employing guinea-pigs and rabbits. Furthermore rats succumb more quickly and a strain may be lost, whereas guinea pigs live for four weeks or longer from which the strain may be recovered at intervals, when parasites are present in the blood. As stated above, *trypanosomes employed in rat tests should be propagated in rats; if at any time a strain is taken from a guinea-pig or rabbit it should be passed at least twice through rats before being used in rat tests in order* to restore virulence to the uniform level for rats. In guinea-pigs the virulence is reduced and as stated in the preceding chapter, it is my custom to pass strains through one or two guinea-pigs, if the virulence for rats becomes higher than usual. The methods employed by Pearce and Brown[1] have proven very satisfactory.

It is a good rule to always inject several animals (mice, rats or guinea-pigs) with varying amounts of blood suspension in order that the animals may not all die at approximately the same time and so make the recovery of the strain uncertain.

Author's Method for Conducting Trypanocidal Tests Employing Rats.—This method[2] was developed in 1914–1915 in connection with chemotherapeutic investigations conducted in coöperation with Dr. Jay F. Schamberg and Dr. George W. Raiziss. It has been in routine use in my laboratory since then and in our work has proven reliable and satisfactory. It yields remarkably uniform and decisive results with a minimum of expense, labor and time and has fulfilled the essential requirements of a routine trypanocidal test.

The Trypanosome.—After considerable experience with *Tr. brucei*, *Tr. equinum* and *Tr. equiperdum* the last mentioned has been found the most useful and satisfactory. *Tr. brucei* infections of rats are ordinarily too severe and sometimes mask feeble but important trypanocidal effects of some compounds. A strain of *Tr. equiperdum* maintained at moderate virulence permits rats to live about six days and this is a sufficiently severe infection. The test may be conducted with any of the pathogenic trypanosomes but

my preference is for *Tr. equiperdum.* If the strain acquires too much virulence by means of a rapid succession of transfers, virulence may be reduced by passing the strain two or three times through guinea pigs or rabbits.

The Animal.—Male albino rats weighing from 150 to 200 grams are employed. The diet is probably not of as much importance as in toxicity tests (see Chapter II), but of course the animals must be in good health and general condition. It is my rule to have the rats under observation for at least a week before employing them in these tests.

Old and heavy animals are sometimes too resistant and the weights of the animals should be approximately uniform, that is, not less than 100 grams or more than 200 grams. Male rats are preferred because female rats of 150 or more grams may be pregnant at the time of the tests and receive a larger dose than they should according to body weight.

Method of Inoculation.—Approximately known numbers of trypanosomes are infected intraperitoneally 24 hours before the medicament is administered. For rats of 100 to 200 grams the number may be 250,000 to 500,000 trypanosomes. *It is particularly important in this method to infect the animals uniformly because the medicament is given arbitrarily 24 hours later;* if the infection is too light or too heavy the results are influenced. In the Hygienic Laboratory method of Voegtlin and Smith numerical infection is much less important because each rat is examined and the trypanosomes counted before the medicament is given.

The counting of trypanosomes and technic of inoculation[3] are as follows:

Seed Animal.—For the purpose of making an accurate count, the seed animal should be one that has not been infected over three or four days as after this time the parasites in the peripheral blood may be very numerous and, what is more important, may be gathered in conglomerated masses which cannot be broken up in the mixing pipet and which render any attempts at counting absolutely worthless.

A preliminary examination of the blood is first made in the usual manner by snipping off the tip of the tail and quickly transferring a drop of the blood on a clean cover glass to a microscopic slide. The weight of the glass is allowed to spread the blood. This preparation is then examined by means of a No. 1/6 objective and No. 4 eyepiece (Leitz), and the number of trypanosomes recorded according to the following scheme:

++++ = very large numbers; cannot be counted.
+++ = large numbers that may be roughly counted (not accurately).
++ = about 10–20 in a field.
+ = about 5–10 in a field.
Few = 1–2 in a field, or in every other field.

This preliminary examination is necessary because it indicates the blood pipet to use, as the red corpuscle pipet for a 1:200 dilution with + + + + and + + + rats, and the white corpuscle pipet for a 1:20 dilution with + + and + rats. This method of recording the count of trypanosomes has been found useful as a routine procedure in the daily examination of large numbers of rats in our chemotherapeutic researches and with due care yields a satisfactory record.

Diluting Fluid.—After some experimentation a fluid has been adopted which serves the three-fold purpose of (1) fixing the trypanosomes and rendering them motionless, (2) quickly staining the trypanosomes so that they are readily seen and counted, and (3) removing the erythrocytes by hemolysis so that the parasites are readily seen in a clear field. It is easily prepared and comparatively stable, remaining clear, without sediment, for

many weeks and months at ordinary room temperature. This fluid is prepared as follows:

Formalin (40 per cent.)	2 c.c.
Glacial acetic acid	2 c.c.
Distilled Water	96 c.c.

Mix and add 2 c.c. carbolfuchsin (Ziehl-Neelson); mix again and filter through paper. This quantity of fuchsin in the presence of formalin gives the fluid a clear, deep-purplish red color. Probably less fuchsin will prove satisfactory to others; more of the dye deepens the color of the fluid unnecessarily and may somewhat obscure the lines of the counting chamber. The formalin quickly destroys the motility to trypanosomes and keeps the fluid free of bacteria and fungi. The container should be well stoppered to prevent evaporation, and it may be advisable to refilter the fluid at occasional intervals.

Voegtlin and Smith[4] state that this fluid sometimes causes a coagulum of unlaked red cells and trypanosomes and they prefer a slight modification prepared by dissolving 0.02 gm. of crystal violet in 200 c.c. of water and slightly warming; 0.7 gm. of sodium chlorid is added, the solution cooled and filtered. Formalin is added (2 c.c. in 200 c.c.) to fix the trypanosomes and prevent their loss of shape. This fluid should be freshly prepared as required.

Counting of the Trypanosomes.—After the seed animal has been selected a count is made of the trypanosomes. The tail is gently whipped back and forth for a minute or two to produce congestion; then, upon very gentle pressure, a large drop of blood appears where the tip has been snipped off. With the red corpuscle pipet, blood is carefully drawn to the mark 0.5 and the diluting fluid to the mark 101, the whole procedure being conducted with the care and exactness required for making an erythrocyte count. If the white corpuscle pipet is used, a large drop of blood is required and hence, before attempting to fill the pipet a free flow of blood must be assured. With this pipet, blood is drawn to the mark 0.5 and the diluting fluid to the mark 11, as in the usual technic for counting leukocytes. As a general rule, the red blood corpuscle pipet is indicated and is more satisfactory than the white blood corpuscle pipet.

The filled pipet is now thoroughly shaken for at least one or two minutes; several drops are expelled, and then sufficient fluid is placed in the chamber and the cover glass accurately adjusted. The slide is allowed to rest on a flat surface for at least ten minutes to permit the trypanosomes to sink down on the ruled off spaces.

By means of the No. 1/6 objective and No. 4 or No. 2 eyepiece (Leitz) and a mechanical stage, all the trypanosomes in the ruled off space (400 small squares) of the Thoma ruling are counted. The trypanosomes are motionless, deeply stained a purplish red, and easily seen and counted. At times they are curled or placed edgewise, but with a clean diluting fluid, to avoid artefacts, and a little experience these forms are readily recognized (Fig. 7). The red blood corpuscles have entirely disappeared, or appear as faint shadows. The leukocytes also are deeply stained, and a total leukocyte count may be made at the same time. A differential leukocytic count is also possible, at least as far as differentiating between the polynuclear and mononuclear leukocytes.

Calculation of the Number of Trypanosomes in a Cubic Centimeter Undiluted Blood.—As each square contains 1/4000 cubic millimeter when the cover glass is properly adjusted, it is necessary to count the trypanosomes in 4000 small squares to obtain the number contained in 1 cubic millimeter

of the diluted blood. By counting the trypanosomes in 400 small squares and multiplying by 10, the approximate number in 4000 small squares, or 1 cubic millimeter, is obtained. By multiplying this figure by the dilution, as 200 if the red blood corpuscle pipet was used, or by 20, in case the white blood corpuscle pipet was used, the number in 1 cubic millimeter of undiluted blood is obtained. Multiplying this figure by 1000 gives the approximate number of trypanosomes in a cubic centimeter of undiluted blood.

Briefly, by rule of thumb, count the trypanosomes in 400 small squares, multiply by 200, and add four ciphers. The result is the approximate number of trypanosomes in a cubic centimeter of undiluted blood.

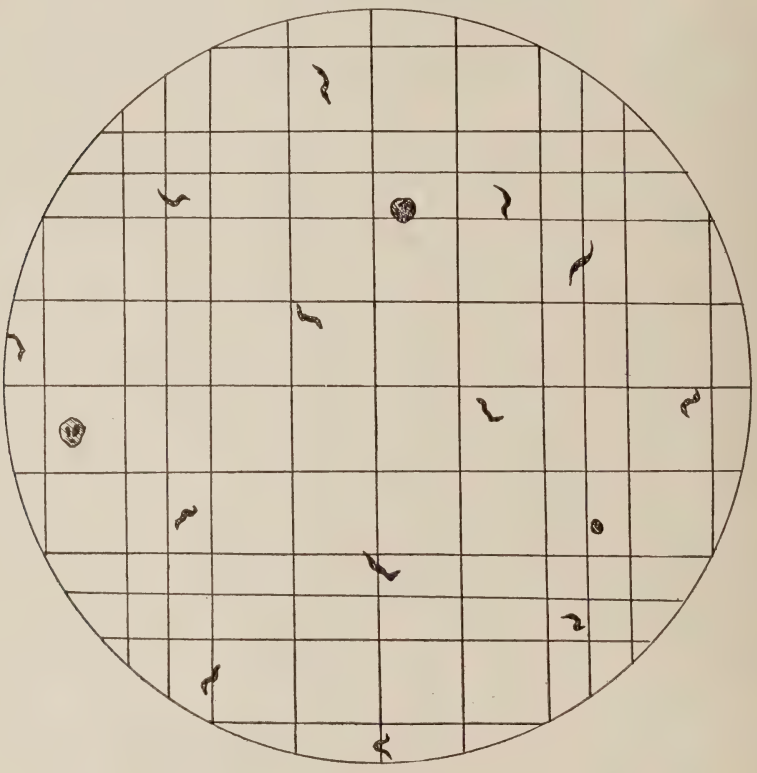

FIG. 7.—METHOD FOR COUNTING TRYPANOSOMES IN THE BLOOD.

A section of the four hundred small squares of the Thoma ruling, showing trypanosomes in blood, diluted 1:200 (182,000,000 per cubic centimeter of undiluted blood), from a ++++ rat infected with *Trypanosoma lewisi*. × 288 (Leitz No. 6, eyepiece No. 2).

If the white corpuscle pipet is used, the calculations are the same, except that the dilution is 1:20. By rule of thumb, count the trypanosomes in 400 small squares, multiply by 20, and add four ciphers.

A question of considerable importance in this connection is whether counts of trypanosomes made with blood from the tail may be accepted as reliable and similar to counts made with blood from the heart, especially as blood for the purpose of transmitting the parasites is obtained from the heart of the seed animal? I have made a series of counts of blood obtained from the tail and from the right and left ventricles of the heart; it was observed that the counts ran fairly parallel, especially in view of the large number of

trypanosomes present and the chances of manipulative error. Frequently counts of blood obtained from the left ventricle showed slightly fewer trypanosomes than those of blood from the right ventricle and tail, but on the whole they were sufficiently close for the purpose of counting trypanosomes in the blood from the tail and using this figure as representing the number present in blood from the heart in the transmission of approximately known numbers of trypanosomes. It must be emphasized, however, that blood from the tail must flow easily and freely before counts are reliable; those from blood obtained after squeezing and massage of the tail are inaccurate and unreliable.

Securing of Infected Blood for Transmissions.—Blood is obtained from the heart of the seed animal. In this way, 0.1 c.c. of blood may be obtained in

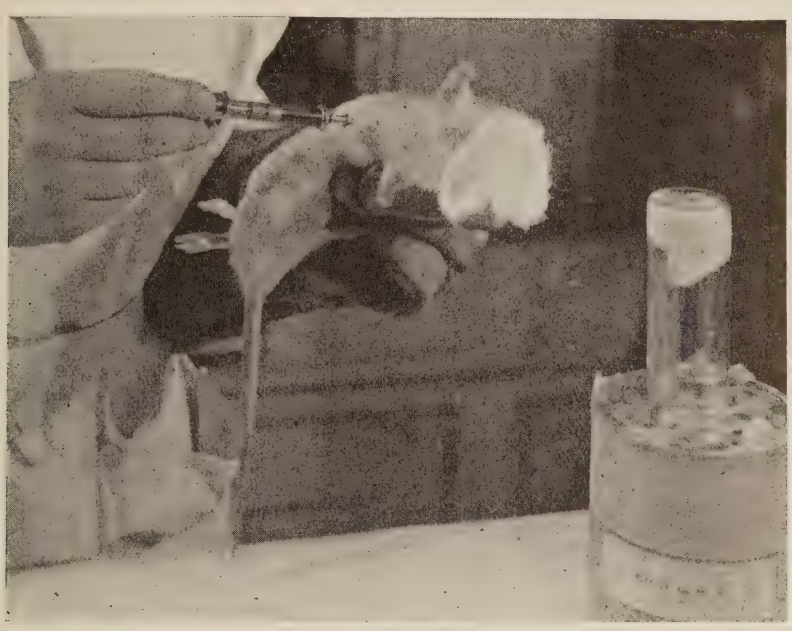

FIG. 8.—METHOD FOR REMOVING BLOOD FROM THE HEART OF A RAT.

an accurate and sterile manner, the success of this method of transmitting known numbers of trypanosomes depending of course upon the operator's success in obtaining the blood accurately and quickly from the heart. There must be no more and no less blood, and the dilutions must be accurate.

This amount of blood is easily obtained from the living rat. If it cannot be drawn accurately, the animal should be killed, the thorax opened, and the blood drawn directly from the heart under the eye of the operator. With a little practice, however, one seldom fails to draw the blood from the living rat, and usually the operation does not appear to injure the animal.

It is necessary to use an accurate and well adjusted 1 c.c. syringe divided into tenth cubic centimeters. I prefer the Record syringe fitted with a No. 22 needle. A proper needle is very important; it must be sharp and sufficiently large to permit the easy flow of blood and yet not so large as unnecessarily to injure the heart.

(1) Warm a test tube containing 10 per cent. sodium citrate in normal salt solution in a Bunsen burner and draw up enough of this into the syringe

to make, when air has been expelled, 0.4 c.c. including the needle. (The sodium citrate prevents coagulation of the blood under isotonic conditions.)

(2) The rat being held by an assistant, or fastened to an operating board, paint the left thorax with tincture of iodin and quickly insert the needle at about the point of maximal pulsation (Fig. 8). By gentle suction on the piston, blood is made to flow into the syringe. If blood does not appear, re-insert the needle in an upward and inward direction without withdrawing it entirely. Draw blood accurately to the 0.5 c.c. mark (=0.1 c.c. blood). Withdraw the needle and draw more of the warm citrate solution to the 1 c.c. mark. This gives a dilution of blood in the syringe equal to 1 in 10. Shake gently in order to mix the blood.

(3) Expel the contents of the syringe into a test tube containing 9 c.c. of warm salt solution and wash out the syringe three or four times with this solution, or the contents of the syringe may be expelled into a tube containing 6 c.c. of warm normal salt solution and the syringe washed out with 3 c.c. fresh warm salt solution into this tube in order better to remove all trypanosomes from the syringe and needle. This gives a suspension of 1:100, and from this tube further suspensions of the trypanosomes may be made in warm, sterile salt solution as required.

If one fails to secure blood in this manner it may be collected more easily as follows:

In an accurately graduated 25 c.c. cylinder place 10 c.c. of warm sodium citrate solution. Sever the vessels of the throat of the animal with sharp scissors and collect the blood by means of a small funnel. Read off the amount of blood obtained and dilute with warm physiological saline solution as required.

Dilution of Infected Blood for Transmission.—A 1:100 suspension of infected blood having been secured, further suspensions may be made by transferring 1 c.c. to a series of test tubes containing 9 c.c. of warm, sterile salt solution. The 1:100 suspension and each succeeding one should be thoroughly mixed by furnishing each test tube with a sterile rubber stopper and then gently agitating the contents with turning up and down until a thorough admixture results. With the final suspensions, a series of rats may be infected by injection of each intraperitoneally with a cubic centimeter or fraction thereof, according to the count.

In conducting chemotherapeutic researches with *Tr. equiperdum*, best results have been obtained when the rats were infected with about 100,000 trypanosomes per animal. With *Tr. brucei* fewer may be used and with *Tr. lewisi* a larger number should be injected.

Method of Infecting Rats.—Rats may now be infected by the intraperitoneal injection of the proper dose of trypanosome suspension. For this purpose, I prefer a 1 c.c. Record syringe fitted with a No. 22 needle. The suspension of trypanosomes should be briefly and gently mixed each time before the syringe is loaded in order to avoid settling. The syringe should be sterile and the technic fairly aseptic, although I have never seen infection of the peritoneum follow when the rat was properly entered. I have not found it necessary to clip the hair or sterilize the skin by washing or even by an application of tincture of iodin, and with due care the intestines are not punctured.

Time Interval between Inoculation and Treatment.—Twenty-four hours later the medicament is administered. During this time trypanosomes have multiplied and an occasional parasite may be found in the tail blood examined microscopically. If rats of approximately the same weight are inoculated with uniform numbers of trypanosomes the resulting infection is

quite regular although the natural resistance of individual animals influences the rate of multiplication and invasion of the blood stream. Brown and Pearce also inject the medicament 18 to 24 hours after intraperitoneal inoculation whereas Voegtlin and Dale infect the animals more heavily and wait until the blood stream has been more extensively invaded with trypanosomes, before treatment is begun. There is however, no essential difference in the end results except that the curative dose in my method is less than in these other methods because fewer trypanosomes require destruction. This subject will be discussed at greater length later on.

Intravenous Injection of Drug.—The rats are kept fasting for at least 12 hours prior to treatment. Each animal is carefully weighed, numbered and recorded. The compound for treatment is prepared in solution and administered according to the body weight of the respective animals. Ordinarily 4 rats are used for treatment with varying amounts of drug and 2 rats kept as untreated controls. Or 4 controls are used for a series of 20 to 40 treated animals.

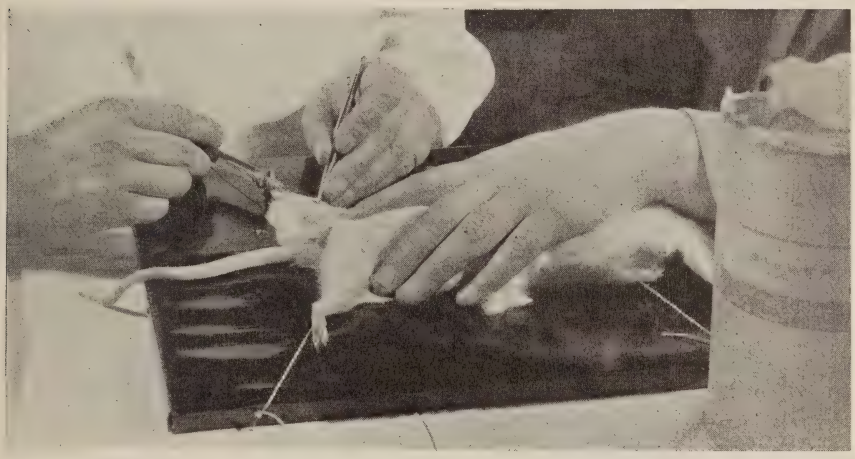

FIG. 9.—METHOD FOR INTRAVENOUS INJECTION OF THE RAT IN TRYPANOCIDAL TESTS EMPLOYING THE FEMORAL VEIN.

The medicament is prepared for each animal in such way that the amount of fluid injected is 1 c.c. Smaller amounts are unadvisable because of the influence upon results if a drop or two is lost in the process of injection.

The injections are given intravenously, the saphenous vein is generally employed, the technic being as follows:

(*a*) The rat is tied on its back to an operating board. This is a simple board covered with white oil cloth for facilitating cleansing and furnished with nails at the four corners for tying the animal. An assistant wearing gloves handles the animal and by means of slip knots the animal is quickly and securely tied.

(*b*) A wad of cotton is now placed under one thigh to render the tissues firm. The assistant places his finger in the inguinal region to make pressure and render the saphenous vein more prominent.

(*c*) The skin is wiped with alcohol and a small incision made at about the middle of the thigh and in line with the vein (Fig. 9). With a little dissection the vein is brought into view and is grasped with a fine pointed pair of forceps and steadied. A suture of black silk may be placed below the point

selected for injection in order to prevent subsequent bleeding. This is advisable when neoarsphenamin is being injected because of the lowered coagulation time of the blood, but otherwise it is not necessary as bleeding usually ceases as soon as the rat is released providing a No. 26 needle has been used and the vein not mutilated with several puctures.

A 1 c.c. syringe fitted with a No. 26 needle is employed, being prepared beforehand and in readiness. The eye of the needle is slowly inserted bevel upwards; the assistant releases pressure in the inguinal region but holds the leg against movement and the injection is slowly given. The vein is now tied off if neoarsphenamin has been injected and the rat is quickly released. With experience an operator and assistant can easily inject 20 rats in an hour.

The wound is not sutured; infection practically never occurs unless some of the solution and especially arsphenamin and neoarsphenamin have been injected in the tissues around the vein and necrosis thereby produced.

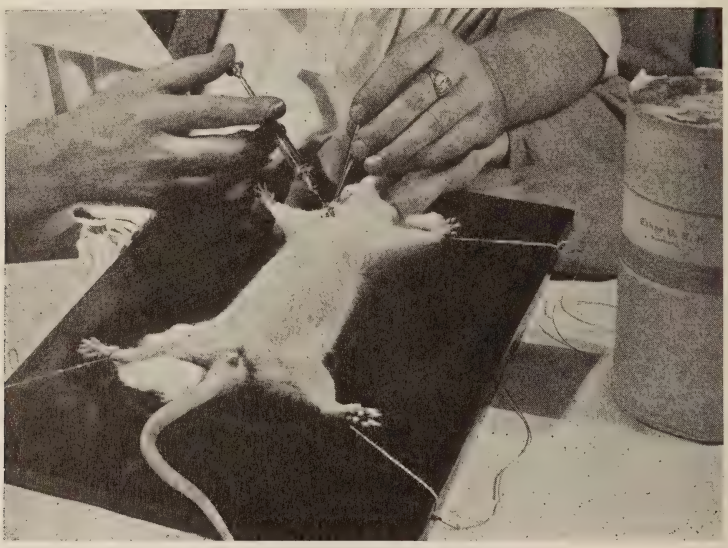

FIG. 10.—METHOD FOR INTRAVENOUS INJECTION OF THE RAT EMPLOYING THE EXTERNAL JUGULAR VEIN.

When the injection has been cleanly and expertly given, healing occurs promptly and without infection.

An *external jugular vein* may be used instead and has the advantage of being larger. For several years I employed one of these veins with uniform success but I now believe that the saphenous vein is to be preferred because there is less bleeding; this is especially true when neoarsphenamin is administered.

The animal is tied to the operating board in the same manner and a wad of cotton placed under one shoulder. The assistant holds the head backwards and to one side with a piece of cotton rendering the tissues of the operative area tense and firm (Fig. 10).

The skin is touched with alcohol and a small incision made just above and about in the center of the area where a clavicle in the human would be situated. The subcutaneous tissues are gently dissected and the vein exposed which becomes very prominent with respiratory movements. It is well not to attempt entering the vein until it is thoroughly exposed as other-

wise one may infiltrate the tissues over and about the vein by failure to enter it properly. As soon as the injection has been given the animal is quickly released and the wound requires no attention as infection practically never occurs and healing is rapid.

Rats and mice may be injected by means of a caudal vein of the tail described in Chapter II. This method is practically the only one employed for the intravenous injection of mice. The veins are quite small, and the injection requires a fine needle and considerable experience.

Study of Effects;—"Minimal Effective Dose" and "Minimal Curative Dose."—The control and treated animals are kept under observation and blood from the tail of each examined daily. *Each animal is kept in an individual cage* because when a group of rats are kept together the stronger and healthier may annoy and finally destroy the weaker and sicker animals. Furthermore treated rats recovering from infection may later become

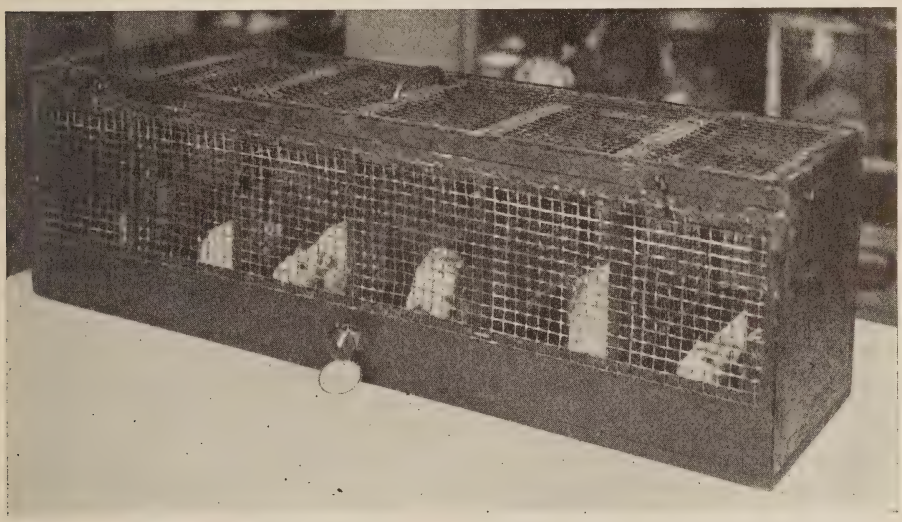

FIG. 11.—CAGE FOR KEEPING RATS SEPARATELY IN TOXICITY AND TRYPANOCIDAL TESTS.

infected by eating rats with trypanosomiasis and this tends to introduce an element of error and irregularity in the results. For these reasons I have found it advisable to keep the animals separate and the cage shown in Fig. 11 which can be made by any carpenter, has been found satisfactory.

The tail blood of each animal is examined daily and the presence or absence of trypanosomes recorded. At least five fields are looked over before a negative result is recorded. If trypanosomes are present they are recorded by the *Few*, +, ++, +++ and ++++ scheme described above.

The untreated controls generally succumb in 5 to 7 days after infection. The survivors among treated animals are kept under observation for at least *three weeks;* trypanosomiasis may develop as late as 15 days after treatment which is 16 days after infection. The majority of animals remaining sterile for this period are cured but I extend the period to 21 days in order to make sure that the dose recorded as "curative" has effected complete sterilization.

A complete test should include controls receiving drug alone (but not infected) as checks upon the toxicity of the compounds being employed; as a general rule, however, toxicity tests are first conducted as described in Chapter II and under such conditions these controls may be omitted.

Of course it is not absolutely necessary to extend a test over a period of 21 days; it may be terminated at any arbitrary time but if this plan is adopted it should not be earlier than the 7th day at which time the controls will have succumbed. If such a plan is pursued the smallest dose of medicament preventing blood invasion is called the "*minimal effective dose*" (M.E.D.); the smallest amount preventing blood invasion for 21 days is designated as the "*minimal curative dose*" (M.C.D.) and rats succumbing after this time are not destroyed by trypanosomiasis but by late toxic effects of the drug injected or some other factor.

Advantages and Disadvantages of the Method; Uniformity of Results.—The advantages of the method are its accuracy, technical simplicity and economy of animals and labor. Ordinarily the doses given to rats vary by 1 milligram per kilogram of body weight but with some substances and particularly arsphenamin and neoarsphenamin, differences of ½ milligram may show appreciable effects upon the infections. With new compounds of unknown trypanocidal activity the usual procedure is to first determine the toxicity followed by a preliminary trypanocidal test in which the range of doses is higher as, for example, 0.001, 0.002, 0.004, 0.008, 0.010, 0.020 gm., etc., per kilogram of rat; when some idea of trypanocidal activity is thereby gained a re-test with closer doses employing 4 rats is done for more accurate data. If it is inconvenient to wait 21 days for the "minimal curative dose" the results may be read at the end of 5 to 7 days as the "minimal effective dose."

Ordinarily, therefore, 6 rats suffice for a preliminary test and 4 rats for a final test. After some experience with the method has been gained, an operator and assistant can easily infect and administer compounds to 30 rats within a total of four hours of working time; this permits the testing of many compounds with a minimum of labor and animals.

Arsphenamin being more stable than neoarsphenamin and much less subject to variations in toxicity and trypanocidal activity when properly preserved in vacuum tubes, has yielded fairly uniform results in trypanocidal tests at intervals over a period as long as seven months. In one of my experiments twelve different tests were conducted with the same lot of arsphenamin; in three of these tests the minimal curative dose was 0.004 gm. per kilogram; in eight tests the dose was 0.003 gm. and in one test 0.002 gm. In the majority of tests therefore, the dose was identical (8 out 12 tests) and the greatest variation over the period of seven months was but 0.002 gm. per kilogram (0.002–0.004 gm.).

A possible disadvantage is that treatment is given before blood invasion has become well advanced. This, however, is not a matter of much importance because it influences only the dose required for sterilization. As shown in the preceding chapter, the amount of trypanocidal substance required for sterilization when given immediately or within four hours after intraperitoneal inoculation, is generally higher than required after an elapse of 24 hours because the drug may be eliminated too rapidly. Likewise the amount required for sterilization after an elapse of 48 to 72 hours and longer is greater than required at the end of 24 hours because more trypanosomes require destruction. For these reasons at least 18 to 24 hours should elapse between infection and treatment but there is no advantage in waiting longer because the results become more irregular. After all the rat test is of value only for determining comparative trypanocidal activities; for results applicable to the actual treatment of human trypanosomiasis or infections of horses (as dourine) and other animals, additional tests employing rats or rabbits are advisable.

With a strain of *Tr. equiperdum* of uniform virulence and with rats of approximately the same age and weight infected with approximately the same number of trypanosomes, all of which are factors easily under control, the results are of acceptable uniformity. Under these conditions the same lot of arsphenamin preserved in vacuum has yielded a minimal curative dose of 0.004 to 0.006 gm. per kilogram of weight when tested at intervals over a period of one month; arsphenamin of manufacture by a second laboratory showed the same trypanocidal dose of 0.004 gm. in all four tests while the product of a third laboratory showed a value of 0.006 gm. in each of three tests and 0.005 gm. in a fourth test. In similar experiments with neoarsphenamin prepared by different laboratories slightly greater variation was noted.

The Arsphenamin Coefficient.—Probably the greatest single factor of variation in conducting trypanocidal tests by this or any other method, is variation in resistance of the strain of trypanosomes being employed. This is not always due to variations in virulence because untreated controls may not die sooner or survive longer than the usual periods of 5 to 7 days. But yet in some unaccountable manner changes in resistance of the strain to arsphenamin and neoarsphenamin may occur. Naturally one first surmises when the resistance is increased, that by accident the seed rat had received an insufficiently sterilizing dose of either compound and the surviving trypanosomes have propogated a race of resistant organisms. But this is apparently not always the case and it is not possible in any biological test employing two living organisms, namely, host and trypanosomes, to secure results of mathematical accuracy.

For this reason I have always included arsphenamin in each lot of trypanocidal tests because the results with arsphenamin indicate how the whole series of tests should be evaluated. Arsphenamin was selected after it was found that the same lot could be kept over a period of many months with no appreciably change in toxicity or trypanocidal activity when properly preserved. It serves in trypanocidal tests as a "coefficient" for expressing the trypanocidal values of other compounds. In this manner it is analogous to the use of phenol in the Rideal-Walker and Hygienic laboratory germicidal tests in which results are compared with standardized phenol and expressed as the "phenol coefficient." Likewise it serves as a constant factor in these tests like standard toxin or antitoxin for the testing of diphtheria and tetanus antitoxins in guinea pigs. *Even if the results are changed by variation in the resistance of the trypanosomes the "arsphenamin coefficient" is not greatly altered.* If the same arsphenamin cannot be carried along from month to month, any good arsphenamin is next best because experience has shown that arsphenamin of different lots possesses fairly uniform trypanocidal activities under proper conditions. Neoarsphenamin, however, varies to a greater extent and is not suitable as a coefficient of trypanocidal activity.

Hygienic Laboratory Method for Conducting Trypanocidal Tests Employing Rats.—In this method which has been developed in the Hygienic laboratory by Voegtlin and Smith in coöperation with Crane, Wright and Connell,[5] treatment is not begun until each rat shows from 100,000 to 300,000 trypanosomes per cubic millimeter of blood, the purpose being to determine the smallest amount of drug capable of killing these numbers. The trypanosomes of each animal must be counted and for this reason the method consumes a good deal of time. The technic is as follows:

Healthy albino rats from one breeding strain and weighing about 50 to 60 grams are put on a diet of milk bread and oats until they reach a weight of

100 to 150 grams, when they are ready to be used in this test. The animals should not be pregnant.

A strain of *Tr. equiperdum* is employed, being propagated in rats. A seed rat showing about 200,000 parasites per cubic millimeter of blood is bled without special asceptic precautions into 5 c.c. of saline solution containing two per cent. of sodium citrate. This suspension is then injected intraperitoneally into rats, using 0.5 c.c. per animal. Twenty-four hours later the rats so injected show 50,000 to 100,000 trypanosomes per cubic millimeter of blood, and die as a rule within two or three days if left untreated. For the tests rats are chosen which show 100,000 to 300,000 trypanosomes per cubic millimeter of blood; they have found that approximately 150,000 give best results. After the rats have been infected it is necessary next day to examine them for trypanosomes, first by the simple microscopical examination of the blood. If trypanosomes are present a count is made; if the number is less than 100,000 treatment is delayed for a few hours. If more than 300,000 are present the rat is not employed. The counts are made by my method previously described.

The drugs are administered by intravenous injection and the time of disappearance of the parasites from the blood stream determined by subsequent examinations and counts. At least two counts are made on the day of injection and a count on the following and second days.

The injection of the drug to be tested is carried out as follows: the drug is dissolved according to the usual procedure in distilled water avoiding all unnecessary shaking and adjusting the concentration in such a way that the desired dose is within 0.3 to 0.9 c.c. An accurately calibrated tuberculin syringe provided with a 26 gauge Luer needle, is then filled with the freshly prepared solution and the drug is immediately injected at a slow rate into the leg vein previously exposed by skin incision. It is not necessary to use anesthesia for this very simple operation. The rat is tied to a board provided with four nails to which the four legs are fastened by means of strings. The number of trypanosomes per cubic millimeter of blood should be within 100,000 to 250,000 preferably between 100,000 to 150,000.

Minimum Effective Dose.—In order to compare the trypanocidal efficienty of various lots of arsphenamin or neoarsphenamin graded doses of the drug are injected into a series of animals. It has been found that a variation of about 50 per cent. between successive doses (1, 1.5, 2, 25, 3, 75, 5, 7.5, 10, etc.) is all that can be expected of the accuracy of the test. This is due to the fact that quantitative differences in the metabolism of the drug and rate of excretion of the arsenic in different rats are sufficiently great to produce considerable variations in parasiticidal action. These variations make it necessary to use at least five rats for each dose. At the end of 24 hours after the injection of the drug the number of parasites in the tail blood is again determined, first by a preliminary examination of a drop for the presence or absence of parasites and then a count of the blood specimen which were found positive in the preliminary examination. The method permits to count with accuracy 1000 or more parasites per cubic millimeter. Below 1000 the count is unreliable and therefore they have refrained from making counts in such cases and merely go by the result of the drop examination, calling it a *trace*, when only one parasite is found in several different microscopic fields of a fairly thick preparation.

The minimum effective dose is the dose required to bring the parasitic count within 24 hours to a trace or negative, or in other words the dose which kills from 100,000 to 250,000 parasites per cubic millimeter of blood. As a

rule the blood is again examined at the end of 48 hours and 72 hours after treatment.

Extensive experience has shown that with arsphenamin and neoarsphenamin the maximum effect upon the parasites is exerted within the first 24 hours, though occasionally a count of 1000 or less may become trace or negative in 48 or 72 hours.

English Method for Conducting Trypanocidal Tests Employing Mice.—The method employed by the Medical Research Council of England for testing the trypanocidal activity of salvarsan and neosalvarsan and devised by Dale and White in coöperation with Burn, Durham and Marchal,[6] is essentially similar to the Hygienic Laboratory method of Voegtlin and Smith except that mice are used.

Tr. rhodesiense and *Tr. equiperdum* have been employed with almost identical results but the latter is now used routinely; comparative tests employing rats and mice yielded closely similar results but the latter has been adopted for routine tests because the toxicity tests are conducted with mice.

The strain of *Tr. equiperdum* is propogated in rats and mice are infected for the tests by intraperitoneal injections of 0.1 c.c. of an emulsion of rat's blood in 1 per cent. citrate saline solution so diluted that the total number of trypanosomes injected is in the neighborhood of 7–8 millions. Two days later mice are selected from the infected group showing 100,000 to 500,000 trypanosomes per c.mm. of blood; it is stated that about two thirds of the number of inoculated mice are generally ready for treatment at this time. The counts are made in the usual manner with blood from the tail diluted with Toison fluid to which a little formalin has been added.

The medicament is prepared in solution and administered by injection into one of the tail veins. The effects are observed by microscopic examination for the presence of trypanosomes in drops of blood taken from the tail and examined fresh 24, 48, and 72 hours after the injection of the drug. The least dose which causes, within 72 hours, a complete disappearance of trypanosomes in the sense that none can be found in a systematic search of the tail blood, is termed the "minimal curative dose."

Author's Method for Conducting Trypanocidal Tests Employing Guinea-pigs and Rabbits.—As previously stated trypanocidal tests employing guinea pigs and rabbits are not required for routine work; these tests are employed only in the special study of medicinal compounds for determining their curative activity in chronic trypanosome infections with pathological changes in the fixed tissues. They are especially desirable, however, for chemotherapeutic studies in the treatment of trypanosomiasis of human beings, as African "sleeping sickness," and in trypanosomiasis of the lower animals, as dourine of horses. They are also applicable in chemotherapeutic studies in the treatment of chronic syphilis of human beings, and with such compounds as arsphenamin and neoarsphenamin in which the measure of trypanocidal activity is acceptable as a measure of spirocheticidal activity. Either *Tr. equiperdum* or *Tr. brucei* may be employed propogated in rats.

Guinea-pigs of approximately 300 grams and rabbits of 1500 to 2000 grams are preferred. Both animals are infected by the intraperitoneal injection of approximately 5 million trypanosomes; there is much less influence upon the results of trypanocidal tests by the numerical strength of the infection than observed in rat tests. It is not absolutely necessary to count the trypanosomes if a ++++ seed rat is selected and bled to death in 10 c.c. of warm citrate saline solution; of this emulsion guinea pigs receive 1 c.c. and rabbits 2 c.c. intraperitoneally.

It is scarcely necessary to state that the results of trypanocidal tests are influenced by the length of interval between injection and treatment. If the medicament is given 24 hours after inoculation the trypanocidal dose is less than if given several days or a week after inoculation; for example, the trypanocidal dose of arsphenamin given intravenously 24 hours after the intraperitoneal injection of guinea-pigs was approximately 0.006 gm. per kilogram of weight; when one week was allowed to elapse before the drug was administered the trypanocidal dose was approximately 0.015 gm. per kilo.

Since the special purpose of the test is to determine the influence of the medicament in the presence of tissue lesions, I allow 7 *days to elapse after inoculation before treatment is begun.*

The medicaments are given intravenously. Each animal is carefully weighed after fasting at least 12 hours and pregnant animals are avoided. The dose is made up separately for each animal so that a given amount is administered per kilogram of body weight in 2 c.c. for guinea-pigs and 5 c.c. for rabbits. In each experiment controls are included consisting of at least 2 infected animals without treatment. Drug controls are not ordinarily required if the doses given are known to be less than the toxic amounts for guinea-pigs and rabbits.

Guinea-pigs are injected by means of a saphenous or external jugular vein, the technic being essentially the same as described for the injection of rats. Rabbits are injected by means of an ear vein.

The animals are now kept under observation for at least 4 to 6 weeks, the blood (obtained from an ear vein of either guinea pig or rabbit) being examined at frequent intervals (usually every other day) and an additional record made of the development of any of the skin, mucous membrane and genital lesions. At the end of this time the spleen of each animal is removed and ground up in about 5 c.c. of sterile saline solution; 1 c.c. of the suspension is then injected intraperitoneally into each of two rats and these are observed for 6 or 7 days for the development of trypanosomiasis. This control test is required before one may be certain that an animal is cured, being anologous in this respect to the removal of lymph-glands and injection into fresh rabbits when conducting chemotherapeutic tests with syphilitic rabbits (see Chapter XXI). Sometimes guinea-pigs and rabbits at the end of 4 to 6 weeks are apparently in good condition and free of blood and tissue trypanosomiasis until the rat test discloses that living trypanosomes are present in the spleen. Emulsions of liver may be used instead of the spleen.

Author's Methods for Determining the Trypanocidal Activity of Substances in Vitro.—During the course of chemotherapeutic studies, compounds possessing a well-defined parasitropic effect may be prepared which prove so highly organotropic or toxic for the test animal that the minute doses tolerated fail to exert an appreciable influence on the parasites. The mercurials, which are known to exert a powerful bactericidal effect *in vitro*, are substances of this class, being so highly toxic that doses greater than 0.0004 gm. per 100 gm. of white rat are apt to prove fatal and yet are too small materially to influence the course of experimental trypanosomiasis.

In order, therefore, to avoid the mistake of discarding new compounds possessing a high degree of trypanocidal activity because they are highly toxic for experimental animals, a study of various methods of determining the trypanocidal activity of a drug, independent to some extent of its toxicity for the body cells of the host, was undertaken. In the event of the preparation of a new compound that is possessed of a high degree of parasitropism, but is also highly toxic, the efforts of the experimental chemotherapeutist are devoted to lowering the toxicity to a sufficient extent to permit of the administration of the drug to living animals.

With the purpose, then, of devising a technic for determining the parasiticidal activity of a chemical independent of its toxicity for body cells, I studied various methods of determining the trypanocidal activity of substances *in vitro*, which have been published in coöperation with Schamberg and Raiziss[7]. There is considerable evidence at hand that substances exhibiting a marked parasiticidal effect *in vitro* are likely to act in a similar manner *in vivo*, provided the toxicity is sufficiently low to permit of the administration of fair-sized doses; this is true to a certain extent of arsphenamin and neoarsphenamin, likewise of ethylhydrocuprein hydrochlorid and other quinin derivatives in the treatment of experimental pneumococcus infections as shown by Steinfield and myself.

Since the cultivation of pathogenic trypanosomes, as *Tr. equiperdum* and *Tr. brucei*, on artificial media yields irregular results, these methods were designed to determine the influence of a drug upon trypanosomes *in vitro*

by loss of motility and structural changes as determined by direct microscopic examination, and more particularly whether or not the trypanosomes were killed as determined by injecting them into rats after they have been exposed to the medicament in test tubes.

Technic of Microscopic Method.—A series of dilutions of the chemical in 0.85 per cent. sodium chlorid or Ringer's solution and twice as strong as those desired for action on the trypanosomes, is prepared in amounts of 0.5 c.c. and placed in small sterile test tubes in a suitable rack in a pan of water at 37°–40°C.

A seed rat carrying the trypanosomes for the tests is selected whose blood, as examined microscopically with a ⅙ objective and No. 4 eyepiece (Leitz) by placing a drop from the tail upon a cover glass and suspending it over a concave slide, shows a large number of active trypanosomes. One cubic centimeter of a 1 per cent. solution of sodium citrate in normal salt or Ringer's solution is placed in a test tube and warmed; sufficient blood is then secured from the heart or tail of the seed rat to give an emulsion of trypanosomes which, when examined as described above, will show at least 10 trypanosomes in each field and particularly at the margin of the drop. The sodium citrate is added to prevent coagulation of the blood, but more than a 2 per cent. solution is not advisable. This blood trypanosome emulsion is kept warm by placing the tube in the water-bath.

Slides having two or more concavities are prepared and ringer with vaselin. With a 3-mm. platinum loop a drop of a dilution of the chemical is placed in the center of a cover glass; the wire is heated and cooled and a drop of the blood emulsion added and mixed in exactly the same manner as in preparing a microscopic agglutination test. The cover glass is then adjusted to a concavity in the slide and carefully sealed with vaselin. The dilution of chemical now acting upon the trypanosomes is doubled. The time when blood and chemical are mixed is carefully noted, and the slide placed on a warm stage of the microscope or in a small oven heated to 37°–40°C. placed alongside of the microscope.

A number of preparations are made as rapidly as possible with the aid of an assistant, including at least 2 controls prepared by mixing a drop of trypanosome emulsion with a drop of warm normal salt or Ringer's solution.

It is advisable to keep the solutions of chemical, the trypanosome emulsions, and the finished slides at body temperature in order to avoid the effect of chilling on the trypanosomes.

At definite intervals, ranging, for example, from 5 to 10 minutes to an hour or longer from the time of exposure of the trypanosomes to the chemical the slides are examined microscopically and compared with the controls.

As a general rule, the controls show active trypanosomes for at least 1 to 2 hours or longer; after this time the movements may become sluggish or cease entirely in a few of the parasites. For the purpose of avoiding error it is my custom to terminate the experiment at the end of 1 hour.

In case the chemical under study exerts an influence on the trypanosomes the parasites first lose their to and fro movements and remain in one position with constant vibratile movement. Later the latter movement becomes more and more sluggish, finally ceasing altogether, and certain structural changes occur. These effects are best determined by inspecting the trypanosomes at the margin of the drop; before motility is regarded as completely destroyed, a number of fields should be carefully inspected.

With practice and assistance a large number of preparations may be made in a short time. It is our custom to permit at least one-half minute for the preparation of each cover glass. As a general rule it is advisable to examine a preparation within 10 minutes of the time when chemical and trypanosomes are mixed; strong dilutions of a trypanocidal substance, as arsenobenzol, produce an effect with a few minutes.

This method is open, however, to some degree of error. The results of experiments with the same substance at different times with the same strain of trypanosomes have been found to vary; hence the results should be interpreted as showing approximately the relative trypanocidal activity of different substances judged solely by their influence on the motility and appearance of the parasites. Loss of motility, however, is not necessarily an indication of the death of a parasite.

Technic of Combined in Vitro-in Vivo Method.—In this method equal parts of varying dilutions of the chemical under study are mixed with blood trypanosome emulsion and kept at 37°–40°C., when the whole or a part of each is injected intraperitoneally into white rats to determine the degree of trypanocidal activity. As a part of the drug is injected, the action of the drug is both *in vitro* and *in vivo* and due care must be exercised against the administration of lethal doses of the drug.

A series of dilutions of the drug under study is prepared in sterile normal salt or Ringer's solution in small sterile test tubes (1 × 6 cm.) and in amounts of 0.5 c.c. The series is placed in a water-bath at 37°–40°C. to be warmed to body temperature.

A rat heavily infected with *Tr. equiperdum* or *Tr. brucei* is selected, and a count made of the number of trypanosomes per cubic centimeter of blood.

Blood is then secured from the heart or vessels of the neck in sufficient sterile 1 per cent. solution of sodium citrate in normal salt or Ringer's solution warmed to 40°C. to give the desired dilution. Each cubic centimeter of this suspension should contain at least 20,000,000 trypanosomes. After a count has been made and the amount of dilution calculated, it is good practice to place the diluent in a small graduated cylinder and bleed the rat from the neck into the cylinder by means of a sterile funnel until the desired amount of blood has been added. This mixture is then gently shaken and afterward kept at a temperature of 37°–40°C. in a water-bath.

At an appointed time 0.5 c.c. of the trypanosome emulsion is added to each tube containing the solution of chemical and to a series of controls containing 0.5 c.c. of sterile normal salt or Ringer's solution. Each tube is gently shaken and then kept in the water-bath at 37°–40°C. for 15 minutes. The trypanosomes should be added to the chemical at intervals of one-half minute, which permits sufficient time for the injection of each.

At the end of the period of exposure 0.5 c.c. of the blood trypanosome chemical mixture is injected into the peritoneum of a rat. One-half minute is assigned for each injection. A 1-c.c. record syringe fitted with a 22 platinum iridium needle is well adapted for the injections. After each injection there is sufficient time to wash out the syringe and needle several times with hot normal salt solution conveniently placed near the operator.

Each rat is then kept under observation for at least 2 weeks and the blood examined daily for trypanosomes. In this manner the degree of trypanocidal activity may be determined according to the time when trypanosomes appear and the duration of life as compared with that of the controls. As a part of the chemical is injected into the peritoneum of the rat, its trypanocidal activity is probably continued *in vivo*.

CHAPTER XI

TOXICITY AND TRYPANOCIDAL ACTIVITY OF DYES

As stated in Chapter V the anilin dyes were among the first substances to command interest in the chemotherapy of experimental infections and especially in the treatment of trypanosomiasis of the mouse and rat. While several were found to possess a high degree of trypanocidal activity none have proven of any particular practical value in the treatment of trypanosome diseases of man and the lower animals, although the early investigations in chemotherapy of experimental trypanosomiasis with dyes proved a wonderful stimulus and aided greatly in establishing some of the fundamental principles of this new field in therapeutic science. Work of this kind necessarily demanded the trial of hundreds of new compounds, and the comparative technical ease of trypanocidal tests and the relatively short time required for the evaluation of results, rendered them of much value.

I have already classified the more important anilin dyes in relation to chemotherapy in Chapter V. Not all have been tried out in trypanosomiasis, only some belonging to the azo and triphenylmethane series receiving much attention. It cannot be too strongly emphasized however, that the method employed for the conduct of trypanocidal tests has a marked influence upon

the results. The organism employed, the test animal, the number of organisms used for producing infection and especially the interval between infection and treatment, are important modifying factors. Therefore, the results recorded in the succeeding pages of this chapter and in Chapters XII to XV should be broadly interpreted. All values expressed by Schamberg, Raiziss and myself or by Voegtlin and Smith are based upon the two methods described in the preceding chapter; European investigators, however, have not always described their methods, but in general terms the tests have been usually conducted with mice by a technic similar to that of mine employing rats.

Toxicity and Trypanocidal Activity of Azo Dyes.—Owing to Ehrlich's interest and pioneer investigations in the staining of cells and particularly the subject of vital staining, studies in the trypanocidal activity of certain dyes early claimed his attention. With the cooperation of Shiga a large number of dye compounds were tested and encouraging results observed with some belonging to the azo group of the benzidine series, especially the *benzopupurin* series. Ehrlich had noted that these dyes remained in the blood for variable periods of time and still longer as granular deposits in certain cells of the internal organs, and these observations indicated a possible therapeutic application. Later Bouffard[1] showed that *trypan-blue* persisted as granules in the epithelium of the collecting tubules of the kidney, the Kupfer cells of the liver and in the connective tissue of numerous organs, the nervous system remaining conspicuously free. Decoloration and elimination of the dye first occurred in the plasma and then the cells. It was work of this kind on vital staining, therefore, that played an important role in early chemotherapeutic investigations.

At this time Ehrlich succeeded in enlisting the aid of Weinberg, an expert in the manufacturing of dyes, and with his assistance the solubility and trypanocidal activity of dyes of the benzidine series was increased by the introduction of sulphuric acid groups resulting in the discovery of a new compound designated as *trypan-red*.

Ehrlich and Shiga[2] found that this dye possessed a low toxicity for mice, the lethal dose by subcutaneous injection being about 0.5 gm. per kilogram of weight. When the compound was administered to mice by subcutaneous injection in doses of 0.05 to 0.5 c.c. of 1 per cent. solution per 20 grams of weight at the same time as the animals were infected with *Tr. equinum*, the mice were not taken ill and survived indefinitely. When treated three days after infection, the majority survived, although relapses occurred which could be controlled or avoided by subsequent injections. Ehrlich and Shiga also found that if mice were fed for two to eight days with cakes containing 0.2 gm. trypan-red that they could not be successfully infected with trypanosomes. With *Tr. brucei*, however, the results were negative both after feeding and subcutaneous injection of the compound, indicating the elective trypanocidal effects of this substance; furthermore, as shown subsequently, trypan-red is ineffective or almost so in *T. equinum* infections of the guinea pig, rat and dog although quite effective for the treatment of mice infected with this trypanosome. Curiously, trypan-red does not readily kill trypanosomes *in vitro* and does not stain the organisms until they are dead. Trypanosomes exposed to the dye *in vitro* however, have their virulence reduced even though they may not be killed.

According to their experiments trypan-red is not trypanocidal in the test tube. For this reason they advanced the theory that the dye engendered or greatly aided in the production of antibodies which constituted the chief trypanocidal agents. Ehrlich[3] later reported that 50 substitution com-

pounds of trypan-red were prepared and tested employing *Tr. brucei*; in all of those possessing some degree of trypanocidal activity the sulphuric acid rests were located in the naphthalene nucleus in the position 3.6 while the newly introduced groups were best placed in the position 7.

In 1906 Nicolle and Mesnil[4] published the results of their extensive studies with the dyes of the benzidine group, including *toluidin* and *trypan-blue*. The toxicity was determined by subcutaneous injection in mice and therapeutic activity by administration to mice infected with different strains of pathogenic trypanosomes, as *Tr. brucei*, *Tr. evansi* and *Tr. equinum*. Their work was especially notable by reason of the fact that they clearly showed the relation between chemical constitution and biological effects, the basis of chemotherapy and the goal of Ehrlich's efforts. For example, it was shown with this group of dyes that for trypanocidal activity the napthalene chains should contain the NH_2 group and at least two SO_3H groups. Dyes without these groups as dioxynapthalene disulphat, chlorooxynaphthalen disulphat and amidonaphthol disulphate usually did not stain the mice and were without trypanocidal activity. On the contrary the naphthylanimes, amidonaphthols, naphthalene diamines disulphat, the trisulphate combined with benzidine bases (toluidin, toluilene diamin monosulphate, etc.) usually stained the mice and proved trypanocidal in varying degree. Moore, Nierenstein and Todd[5] likewise found that the NH group in the aniline dyes was the active trypanocidal or "trypanophobe" group. Of these dyes belonging to the benzidine series trypan-red and trypan-blue have commanded most attention and especially the former. Trypan-blue in common with trypan-red, has a sulphuric acid radical adhering to the naphthalene ring occupying the position 3.6; as shown by Ehrlich and von Weinberg all the effective benzidine dyes show this position of the sulphuric acid radical.

The first indication of the importance of the ortho position was furnished by these studies with trypan-red and trypan-blue and their homologues, in which the azo derivative in the ortho position enters into the amido group of naphthalin.

Both of these dyes possess feeble trypanocidal activity; as shown by Vassal[6] trypan-blue is also effective against *Sp. recurrentis* in rats.

From the practical standpoint, however, trypan-red and trypan-blue have not proven of value in the treatment of trypanosomiasis of human beings or the lower animals, the arsenicals having proved more effective.

Toxicity and Trypanocidal Activity of the Triphenylmethane and Other Dyes.—These dyes were first studied by Wendelstadt and Fellmer.[7] Malachite green has proven too toxic and a reduction in toxicity by the introduction of a sulphuric acid molecule also results in a reduction of the trypanocidal effects. Ehrlich has observed that this was true of a series of sulpho acids of the basic dyes. The introduction of a carbonic acid group results in a reduction of trypanocidal activity, as in the case of *chrome-blue*, *chrome-violet* and *azo green;* likewise if a dydroxyl group is introduced, toxicity is reduced but likewise trypanocidal activity as in the case of tri-meth-oxy-para-rosanilin and tri-chlor-para-rosanilin.

Brilliant green was effective against experimental *Tr. brucei* infections in rats and monkeys when administered in repeated doses; negative results were observed with a dog. Microscopical examination of the blood during treatment showed morphological changes in the trypanocomes brought about by the dye. Similar results were observed by Weber and Krause.[8]

Ehrlich also found that derivatives of rosanilin as *hexamethyl-violet* and *hexaethyl-violet* possessed some trypanocidal activity in mice but all of these

showed a tendency for the production of extensive necrosis when injected subcutaneously.

A distinct advance was made with the discovery of *parafuchsin* by Ehrlich and more especially a halogenized derivative of this dye designated as "*tryparasan*" and discovered by Bender, in which chlorine enters in ortho position to the NH_2 group. Tryparasan has been studied by Roehl[9] who found that while mice do not bear more than 1 c.c. of 1:1000 to 1:1200 dilutions of parafuchsin per 20 grams of weight, tryparasan is well borne in dilution of 1:500. One injection of parafuchsin in the maximum tolerated dose delays trypanosomiasis in mice infected with *Tr. brucei* for 14 to 17 days but does not cure unless repeated doses are given. One injection of tryparasan, however, may bring about a complete cure. Both parafuchsin and tryparasan, however, may bring about a complete cure. Both parafuchsin and tryparasan are well borne when fed to mice and favorably influence trypanosome infections by this route of administration; 1 gram is dissolved in 90 c.c. of alcohol and 10 c.c. of oleic acid. Cakes are saturated with 1 c.c. of this mixture carrying 0.010 gm. of the dye. Marks[10] also found that feeding the drug favorably influenced trypanosome infections.

Weber and Krause[11] and Brieger and Krause[12] have studied the biological effects of some dyes belonging to the *acridin, safranin* and *euhordine* series. Especially favorable results were observed with *trypasafrol* of the safranin series, when fed to rats and guinea pigs within twenty-four hours of the time of infection with *Tr. brucei.* Dyes of the safrine series containing a combination of trivalent and pentavalent N were generally non toxic and effective in feeding experiments. The substitution of methyl groups for the H atoms in the animo groups usually resulted in a loss of trypanocidal activity and an increase of toxicity. When an H atom of the amido group was replaced by an acetic acid group, trypanocidal activity was likewise diminished and toxicity increased.

Toxicity and Trypanocidal Activity of "Bayer 205."—Recently a new compound designated as "Bayer 205" has been found to possess well marked curative activity for experimental trypanosomiasis. The exact composition of the substance is not known. The compound has been reported as successful in the treatment of trypanosomiasis of human beings and the lower animals and I shall refer to it again in Chapter XX.

Strictly speaking this substance, discovered by Handel and Joetten in 1920, is not a dye but a colorless, water soluble salt of a complex sulphonic acid. It is apparently one of a long series of compounds formed of chains of aminobenzoyl radicles, united by amid linkages, with a central urea linkage and terminal sulphonic acid groupings. The exact composition is a trade secret but it would appear that Fournier's "309" is of similar composition and action.

"Bayer 205" rapidly cures mice, rats, rabbits and dogs infected with several different strains of pathogenic trypanosomes; infected horses and oxen are cured with difficulty or not at all. Mice infected with *Tr. lewisi* are usually not cured. It has little or no effect *in vitro* suggesting that its curative activity requires the cooperation of the tissues of the host.

One of the remarkable properties of this substance is the long persistence of its effects. While a mouse or rat may be cured in a few days yet they cannot be re-infected for weeks or months and during this time their serum or extracts of certain organs injected into other infected animals results in curative effects. The substance has a large molecule but is extremely soluble in water and readily diffusible through collodion membranes. It is difficult to understand therefore, why it persists in the cells. It has been suggested

that the compound is in the blood and cells in combination with proteins because after standing an hour or two in contact with serum, the compound no longer passes through collodion filters and if the proteins are coagulated by heat, it is not found in the filtrate.

According to Wenyon[13] the maximum tolerated dose for mice by subcutaneous injection is about 0.5 gm. per kilo and the minimum curative dose for *Tr. equiperdum* infections is about $\frac{1}{60}$th this amount. According to Haendel and Joetten[14] and Mayer and Zeiss[15] the compound is active against experimental infections produced by *Tr. brucei, Tr. equinum, Tr. rhodesiense* and *Tr. gambiense,* but not for *Tr. lewisi* and *Tr. cruzi.* Hesselbach[16] found that $7\frac{1}{2}$ per cent. solutions destroy trypanosomes *in vitro* in 25 to 60 minutes. According to Mayer and Menk[17] the compound may be found in the blood (in union with the serum proteins) thirteen days after injection and in the urine twelve days. After the administration of 2 grams by mouth it was found in the serum for eight days.

Mechanism of Trypanocidal Activity of Dye Compounds.—The exact mechanism of the trypanocidal activity of various dye compounds is unknown. Ehrlich and Shiga observed early in their work that solutions of trypan-red possessed but slight trypanocidal activity in the test tube and Ehrlich assumed that its trypanocidal activity in the body was due to the production of new compounds analogous to the formation of the trypanocidally active "oxid" compounds from the arsenicals of the arsenobenzol group by processes of oxidation in the body. In regard to the benzidin dyes Ehrlich has assumed that their activity may be directed toward preventing the multiplication of trypanosomes since Busck showed that free living parasites in solutions of trypan-red may be prevented from dividing and multiplying even though motility and life are not influenced. Nierenstein has expressed the opinion that the amino group of such dyes as trypan-red, Afridol-blue, Afridol-violet and parafuchsin, is directly trypanocidal.

Influence of Dyes upon the Immunity Following Recovery in Experimental Trypanosomiasis.—In 1904, Ehrlich and Shiga[18] discovered a new mechanism having a bearing upon the action of trypan-red in trypanosomiasis of mice. It was observed that mice infected with *Tr. equinum* and cured with one or more injections of trypan-red possessed an immunity to re-infection lasting eighteen to twenty days. In other words, as a result of the cure a temporary immunity had developed, although no signs of immunity developed among untreated mice and none of the untreated animals ever recovered or even developed a chronic infection. Attempts to prolong the immunity by repeatedly infecting and curing mice in the course of a number of weeks, were not very successful. Subsequently, Ehrlich[19] studied the immunity which followed the cure of *Tr. brucei* infections, and found the immunity of shorter duration (about ten days). According to Ehrlich, the duration of the immunity depends upon two factors: (1) the height of the immunity reached, and (2) the virulence of the trypanosomes employed to overcome the immunity. The higher the virulence of the organisms, the shorter the immunity.

Ehrlich and Shiga showed that this immunity after cure with trypan-red was not due to unexcreted dye as is probably the case of "Bayer 205," since normal animals first treated with the dye could be infected although the incubation period may be prolonged.

Halberstaedter[20] then discovered that the immunity was specific. A mouse cured of *Tr. equinum* infection was susceptible to *Tr. equiperdum* and upon being cured of this infection was in turn susceptible to *Tr. brucei.* Ehrlich, however, was not of the opinion that this reaction would serve to differentiate among strains of trypanosomes belonging to different species because the reaction appeared to be too delicate.

At this stage the subject was very thoroughly studied by Terry[21] who employed three different strains of *Tr. evansi* and a single strain each of *Tr. equiperdum*, *Tr. equinum* and *Tr. brucei*. The therapeutic agents employed were amidonaphtol disulphonic acid 1.8.3.6 plus dichlorbenzidin, arsacetin, trypan-red, arsenophenylglycin and various combinations. Best results were observed by employing one of the dyes, either alone or in combination with arsacetin.

Terry was able to confirm the extreme delicacy of the immunity in that mice recovering under treatment from one strain of *Tr. evansi* were still susceptible to other strains of these trypanosomes and by means of this immunity reaction it was apparently possible in a number of instances to separate in purity organisms that had been mixed *in vitro*.

Immunity was demonstrated with all strains and appeared to be a general phenomenon. As a rule it developed early, being detected at times between the second and third days after treatment. The immunity, however, was always temporary and rarely lasted beyond twenty days. Best immunity followed the cure of *Tr. evansi* infections and in general terms was better after the cure of virulent infections than after infection with less virulent trypanosomes.

Influence of Dyes upon Antibody Production in Trypanosomiasis.—The mechanism of this peculiar immunity following recovery from trypanosomiasis under treatment with dyes alone or in combination with arsenical compounds, has never been thoroughly determined. Apparently the medicament either (1) lowers the virulence of the parasites and thereby affords the cells of the host a better opportunity of protecting themselves with the production of immune substances; or, (2) the medicament causes the more rapid release of antigenic substances from the parasites; or, (3) the medicament stimulates the body sells to a more rapid and efficient production of antibodies.

Whether the immune substances are present in the blood of the recovered animals or remain in or upon the body cells has not yet been satisfactorily determined, although some experiments have shown that the serum is trypanocidal. Franke[22] for example, has shown that the serum of a monkey cured of *Tr. equinum* infection, was definitely trypanocidal and that the trypanosomes may develop a resistance or "fastness" to these serum antibodies. I have also found trypanocidal substances in the sera of animals recovering from *Tr. equiperdum* infections as the result of treatment with arsphenamin and neoarsphenamin.

Acquired Resistance of Trypanosomes to Dyes.—I have already discussed in Chapter I this interesting phenomenon which bears a very important relation to the chemotherapy of disease. Franke and Rohl working in Ehrlich's laboratory, discovered that the reason why mice infected with *Tr. brucei* and treated with parafuchsin could ultimately succumb to a recurrence of the infection in spite of treatment with more parafuchsin, was because the organisms had acquired a "resistance" or "fastness" against the effects of parafuchsin. When these trypanosomes were injected into fresh mice the infection was from the very beginning uninfluenced by parafuchsin, administered either by feeding or by injection. Rohl so increased the "resistance" of this strain that on inoculation into animals fed with parafuchsin for days or even weeks beforehand, the infection proceeded as in normal mice, whereas mice so treated and inoculated with a normal strain were protected against infection in 90 per cent. of cases.

Browning[23] succeeded in creating a strain of *Tr. brucei* resistant to trypan-blue in four weeks and resistance to trypan-red in two weeks.

A strain rendered resistant to parafuchsin was also resistant to Dobners violet. A trypan-blue resistant strain was found resistant to trypan-violet and to trypan-red, and the trypan-red resistant strain was resistant to trypan-blue. This group resistance indicates therefore, that the fastness is not absolutely specific but is present in more or less degree for substances of the same chemical type. In the case of these benzidin dyes the phenomenon is of much interest inasmuch as the only feature in common to all is the presence of sulphonic radicals (HSO_3) in the position 3, 6 in the naphthalin-nuclei of the side chains.

However, when the chemical compounds are unrelated, group resistance is not found. Strains of trypanosomes resistant to the dyes as parafuchsin, trypan-red or trypan-blue are just as susceptible to atoxyl or other arsenical compounds as normal strains; a single strain may, however, be rendered resistant to a dye and an arsenical as previously mentioned and when such a strain is inoculated into mice, or, when mice are infected with two different resistant strains, the two varieties behave as if they were distinct species, even though derived from the same original strain. Browning and Gulbranson[24] recently showed that mice protected against infection with virulent *Tr. brucei* by feeding them with parafuchsin before inoculation, could be infected by inoculating them with a parafuchsin-resistant strain. In other words parafuchsin stored in the tissues was trypanocidal for a normal strain, but ineffective against a resistant strain.

Once acquired the resistance to dyes persists for long periods of time. Browning records that a trypan-blue-resistant strain was still highly resistant after eighty passages extending over six months. So also, after five passages through rabbits over a period of five months, the high specific resistance to trypan-blue was still retained.

CHAPTER XII

TOXICITY AND TRYPANOCIDAL ACTIVITY OF ARSENICAL COMPOUNDS

Trypanocidal tests with the arsenical compounds have long been recognized as possessing particular and practical value, not only in relation to chemotherapeutic investigation but especially in relation to the development of compounds for the treatment of syphilis, since it has been found that with these compounds there is relationship between trypanocidal and spirocheticidal properties.

Toxicity and Trypanocidal Activity of Inorganic Compounds of Arsenic. The inorganic compounds of arsenic possess but feeble trypanocidal activity even in doses approaching the maximum tolerated amounts. A single dose usually does not influence either the severity or duration of trypanosomiasis in rats infected with *Tr. brucei* or *Tr. equiperdum*, although repeated doses in sublethal amounts may prolong the lives of experimental animals.

Laveran and Mesnil[1] administered *arsenious acid* (lethal dose 0.015 to 0.020 gm. per kilo) to rats, mice and dogs infected with *Tr. brucei* or *Tr. equinum* and prolonged their lives but never effected a complete cure, the animals dying of poisoning if too much arsenic was administered and of trypanosomiasis if treatment was interrupted. Loeffler and Rühs[2] claim to have succeeded in curing guinea-pigs, rabbits and rats infected with *Tr. brucei* by administering arsenious acid intraperitoneally in 3 to 5 doses of 0.005 to 0.0075 gm. per kilogram. In the experiments of Schamberg, Raiziss and myself, conducted with rats infected with *Tr. equiperdum*, the administration of arsenious acid only prolonged the lives of animals for a few days but never effected a complete cure; *sodium arsenite* (maximum tolerated dose 0.003 to 0.005 gm. per kilogram), in which arsenic is present in trivalent form and *sodium arsenate* (maximum tolerated dose 0.040 to 0.050 gm. per kilogram), in which arsenic is present in pentavalent form, never proved effective in single large doses although in repeated smaller doses the lives of the animals were sometimes prolonged by several days.

The inorganic compounds of arsenic, therefore, including both the highly toxic trivalent compounds of arsenious acid and the less toxic pentavalent compounds of arsenic acid, possess but slight or no demonstrable trypanocidal activity in acute fulminating infections as in mice and rats infected with *Tr. brucei*, *Tr. equinum* or *Tr. equiperdum;* in chronic tissue infections in guinea-pigs and rabbits with these trypanosomes, it is possible to demonstrate slight degrees of trypanocidal activity by administering repeated doses in amounts approaching the maximum tolerated doses. Indeed, Laveran and Mesnil had been influenced to undertake a study of the trypanocidal activity of the arsenicals by the favorable reports of Lingard[3] and Bruce[4] on the treatment of surra and nagana with arsenic.

Toxicity and Trypanocidal Activity of Organic Compounds of Arsenic; *Atoxyl.*—The results of toxicity and trypanocidal tests with *atoxyl* or sodium arsinalate (sodium salt of 4-aminophenyl arsonic acid) have varied greatly according to the chemical purity of different lots, the maximum tolerated dose for rats by intravenous injection being given as 0.05 to 0.150 gm. per

kilogram (general average about 0.150 gm.). Although discovered by Béchamp[5] in 1860 by combining anilin and arsenic acid and first regarded as a simple meta-arsenic acid anilid, it was not until 1907 that Ehrlich and Bertheim discovered that it was an amino derivative of phenylarsonic acid and opening up a large field for preparing new compounds by substitutions in the amino group.

Thomas,[6] in 1905, studied its toxicity and trypanocidal activity quite extensively in monkeys, dogs, rabbits, guinea-pigs, rats and mice infected with *Tr. gambiensi, Tr. evansi, Tr. brucei, Tr. equinum, Tr. equiperdum* and *Tr. dimorphon.* According to his experiments the drug had no appreciable effect upon the trypanosomiasis during the first three hours after injection, but after four to five hours the parasites appeared to be affected because their movements became less rapid with alterations in shape and size. After seven hours, their numbers in the peripheral blood were decreased with total disappearance after eighteen hours when a sufficiently large amount had been injected. Similar results were observed with trypan-red, only the trypanocidal effects were slower, requiring forty-eight hours; at this time Thomas suggested that a combination therapy of atoxyl and trypan-red may be efficacious in the treatment of trypanosome infections of man. Koch,[7] in 1907, tried atoxyl in the treatment of African sleeping sickness on a large scale and his first report inspired great hopes for success, but later it was found that relapses commonly occurred and that large doses may produce optic atrophy. I shall refer to this work again in the succeeding chapter. Uhlenhuth, Gross and Bickel,[8] in 1907, found that the administration of atoxyl in dose of 1 c.c. of a 1 per cent. solution to rats by subcutaneous infection on each of three successive days preceding infection with *Tr. equiperdum* did not prevent the development of a fatal trypanosomiasis. Better results were observed when a dose corresponding to about 0.2–0.3 gm. per kilogram of weight was given at the same time as the infection or smaller doses at intervals after infection. Similar results were observed by Marks, Weber and Kraus, Tsuzuchi, Voegtlin and Smith,[9] and Schamberg, Raiziss and myself. The total of these investigations have in general terms confirmed the work of Thomas, Uhlenhuth and their associates proving the trypanocidal activity of atoxyl in sublethal amounts for different pathogenic organisms in rabbits, rats and mice and for *Tr. equiperdum* infections of rats, the chemotherapeutic index being about 2.5, as shown in the following equation:

$$\frac{\text{Maximum tolerated dose: 0.150 gm. per kilogram}}{\text{Minimal curative dose: 0.06 gm. per kilogram}} = 2.5$$

Arsacetin, or sodium acetyl arsanilate, the sodium salt of 4-acetyl-aminophenyl arsonic acid, is a compound closely allied to atoxyl and was first prepared by Ehrlich and his associates.

The biological properties of this substance have been studied more extensively in relation to spirochetic infections and will be referred to in more detail in Chapter XXIII. Voegtlin and Smith have observed that it is considerably less toxic than atoxyl and more trypanocidal, possessing a chemotherapeutic index about five times higher than atoxyl. Browning[10] found that the maximum tolerated dose for mice by subcutaneous injection was about 3.0 grm. per kilogram of weight and that mice infected with *Tr. brucei* or *Tr. equiperdum* could be cured by the subcutaneous injection of 1.2 to 2.0 grm. per kilogram. Browning also observed practically the same toxicity and trypanocidal properties with a *para-oxy-benzylidene derivative of atoxyl.*

The cacodylates, aliphatic compounds containing arsenic in the pentavalent form, are close derivatives of arsenic acid. By substituting two methyl groups for two hydroxyl groups in arsenic acid, *cacodylic acid* is formed, and by further substitution of sodium for the hydrogen of the remaining hydroxyl group, *sodium cacodylate* is formed. Castelli,[11] Schamberg, Raiziss and myself,[12] Voegtlin and Smith[13] have found cacodylic acid and sodium cacodylate of low toxicity (0.2 gm. per kilogram), probably due to the fact that reduction in the body occurs slowly and a large percentage may be eliminated unchanged; however, trypanocidal activity is likewise almost absent and even doses as large as the maximum tolerated amounts have been found without appreciable effect in rats infected with *Tr. equiperdum* and *Tr. brucei*. Sodium cacodylate has been widely employed for the treatment of syphilis and doubtless does exert some degree of curative activity, but its use is not now justified in view of the fact that it has been demonstrated that its spirocheticidal activity, as well as its trypanocidal activity, is very slight and greatly superseded by arsphenamin and neoarsphenamin.

Sodium methyl arsenic acid or "arrhenal" is closely related to cacodylic acid, differing from sodium cacodylate in having one of its methyl groups replaced by an NaO group. This substance was introduced as a substitute for sodium cacodylate and at one time attracted considerable attention in the treatment of syphilis and human trypanosomiasis. It has been studied by Laveran and Mesnil, Castelli and Voegtlin and Smith; while somewhat less toxic than cacodylic acid, it has likewise been found ineffective in the treatment of trypanosomiasis of the rat and mouse even when administered in doses as high as the maximum tolerated amounts.

The same has been found true of another homologue of cacodylic acid, namely, *disodium ethyl arsonate* or *"mon arsone,"* which differs from "arrhenal" in having the methyl group replaced by an ethyl group. I have found that the maximum tolerated dose of this substance for white rats by intravenous injection is about 0.200 gm. per kilogram of body weight, but doses as high as 0.150 gm. per kilogram are without appreciable effect upon the course of *Tr. equiperdum* infections of rats.

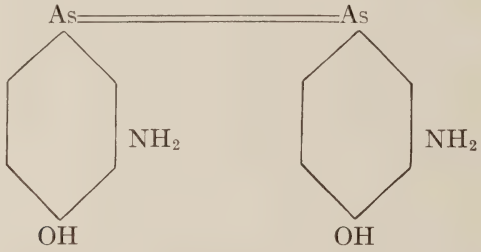
Phenylglycin-p-arsonic Acid and P-arsenophenylglycin.—As will be discussed shortly Ehrlich explained the parasiticidal activity of atoxyl on the basis that in the body it was reduced to the more active trivalent form and this led him to study other aromatic compounds in which the arsenic is trivalent, resulting in the discovery of phenylglycin-p-arsonic acid, an important derivative of arsanilic acid. On reduction of this substance by sodium hydrosulphite, a trivalent compound called *p-arsenophylglycin* is obtained representing the arsenobenzol type of organic arsenical compounds. In this type two arsenic atoms are linked together by a double bond, and each is coupled to the benzol nucleus by a single linkage.

In phenylglycin-p-arsonic acid the arsenic is in pentavalent form; Voegtlin and Smith found the lethal dose for rats by intravenous injection to be about 2.06 gm. per kilogram of body weight and the curative dose for *Tr. equiperdum* infections about 1.03 gm. per kilogram giving a chemotherapeutic index of about 2. The trivalent compound p-arsenophenylglycin is more active than its sodium salt, sodium-p-arseno-phenyl-glycinate, number 418 in Ehrlich's series, and appearing under the name of "spirasyl." Roehl,[14] Tsuzuchi and Voegtlin and Smith have studied its toxicity and trypanocidal effects and the latter found that it possessed a chemotherapeutic index of 16, which is quite high.

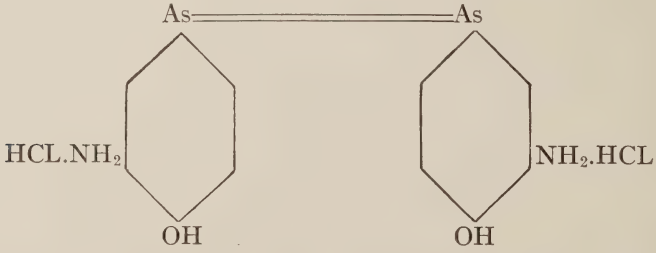
Neurotropism of Arsenical Compounds in Mice.—Mention may be made at this time of the peculiar series of symptoms sometimes produced in mice

by the administration of some of the pentavalent arsenical compounds first described in 1907 by Mesnil, Nicolle and Aubert[15] in rats treated with atoxyl. Browning states that this condition was particularly likely to develop after the administration of arsacetin to mice. General muscular tremors develop and especially characteristic is a jerking hyper-extension of the head, causing the animals to look up into the air. Three or four days later the mice begin to behave in a manner indistinguishable from that of Japanese dancing-mice. In their glasses or on the open floor they go round in circles for hours at a stretch and seem to prefer one direction making only occasionally a few reverse turns. This condition may persist indiminished in animals under observation for many months and is apparently due to the effects of arsenic upon the higher nerve centers as discussed in Chapter LI.

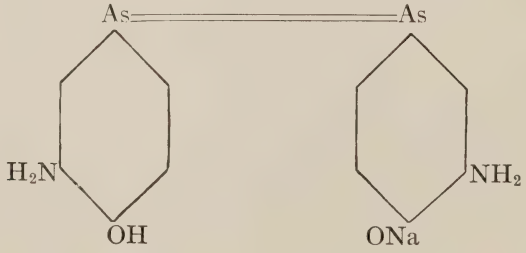
Toxicity and Trypanocidal Activity of Arsphenamin (Salvarsan).—By further varying and changing the position and kind of sidechains, Ehrlich and Bertheim finally produced a new compound, the 606th of their series. The base of this substance, is 3, 3-diamino- 4, 4-dihydroxyarsenobenzene and the dihydrochlorid is the salt employed in the treatment of syphilis, being commonly designated as "salvarsan," "606" or "arsphenamin," the chemical constitution of the base being as follows:



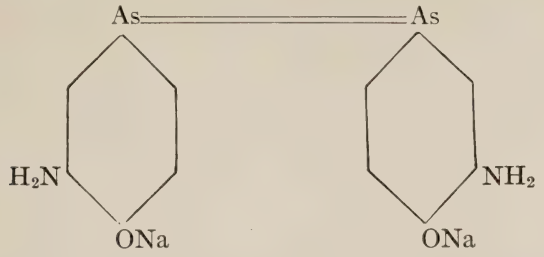
The dihydrochlorid is the form of arsphenamin or salvarsan that appears on the market, its chemical constitution being as follows:



When dissolved in water the solution of this substance is acid and highly toxic; before administration, therefore, the solution requires neutralization with sodium hydroxid. If just enough alkali is added to effect neutralization the mono-sodium salt is produced:



A slight excess of alkali produces the disodium salt, and in this form arsphenamin (salvarsan) is least toxic:



But few medicinal compounds have been studied as extensively as arsphenamin both from the standpoint of toxicity for man and the lower animals

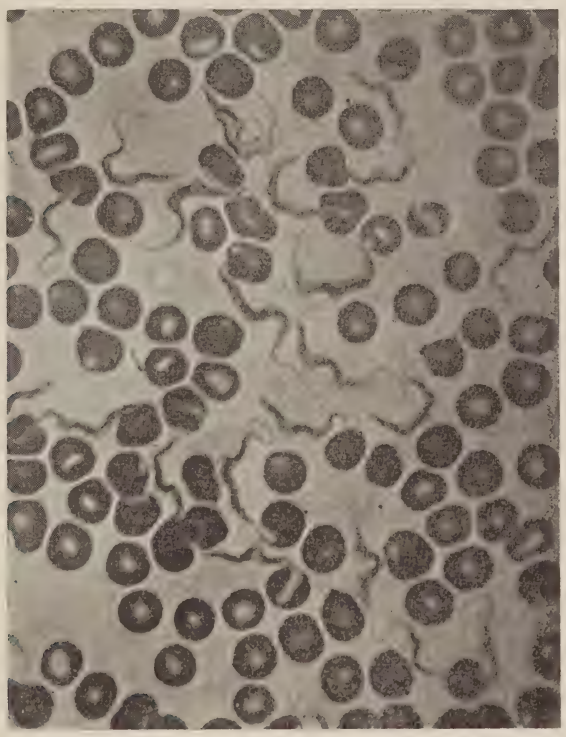


FIG. 12.—BLOOD OF RAT WITH TRYPANOSOMIASIS.
Film prepared four days after intraperitoneal inoculation with *Tr. equiperdum.*

and for curative activity in experimental trypanosomiasis especially in the mouse and rat.

Toxicity for human beings is discussed in more detail in Chapters XLV and XLVI, but here it may be stated that when alkalinized (disodium) solutions of arsphenamin are administered to white rats by intravenous injection as described in Chapter II, the drug is well tolerated in amounts of 0.120 gm. per kilogram of weight. It is required by the U. S. Public Health Service that every lot of arsphenamin employed in the treatment of syphilis shall be borne by white rats for two days, in at least this amount; as a matter of

fact, however, in most instances the arsphenamin being prepared in this country at present is tolerated by rats in doses ranging from 0.120 to 0.150 gm. per kilogram and in exceptional instances even in slightly larger amounts.

Trypanocidal tests for measuring the therapeutic activity of arsphenamin (salvarsan) were first employed (1915) on a large scale in this country by the writer in coöperation with Schamberg and Raiziss.

In general terms the trypanocidal activity of alkalinized (disodium) solutions of arsphenamin (salvarsan) as determined by my method for *Tr. equiperdum* infections of rats is approximately 0.002 to 0.003 gm. per kilogram of weight (Figs. 12 and 13). In a study by Schamberg, Raiziss and

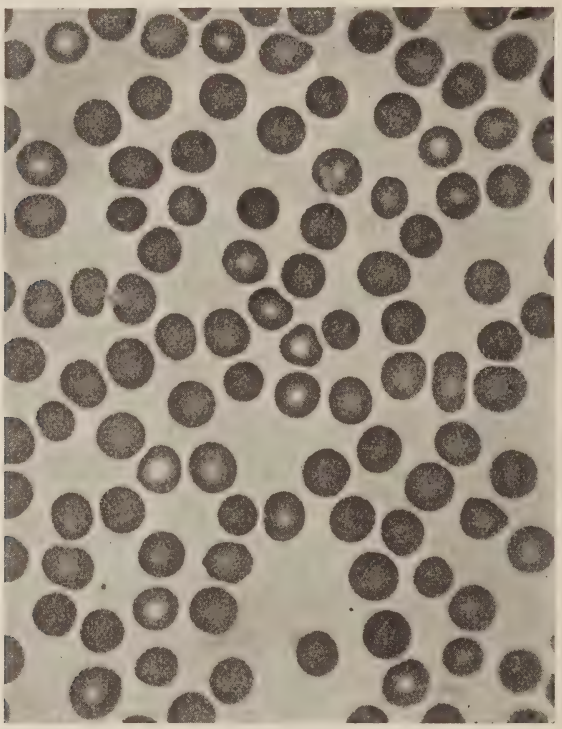

FIG. 13.—TRYPANOCIDAL ACTIVITY OF ARSPHENAMIN.
Blood of same rat shown in Fig. 12 twenty-four hours after the intravenous injection of arsphenamin.

myself[16] of the trypanocidal activity of the arsphenamin (salvarsan) prepared by six different laboratories including the original Ehrlich-Hata preparation as well as that prepared by ourselves, the average trypanocidal doses per kilo of weight varied from 0.0018 to 0.0026 gm. per kilogram.

At the time these tests were made (1919) the average toxicity of the products of different laboratories for white rats was approximately 0.105 gm. per kilogram of body weight giving the following chemotherapeutic ratio:

$$\frac{\text{Maximum tolerated dose: 0.105 gm. per kilogram}}{\text{Minimal curative dose: 0.0023 gm. per kilogram}} = 45.6$$

At the present time (1925) the toxicity of arsphenamin tends to be somewhat less than in former years, averaging about 0.130 gm. per kilogram of body weight and yielding a chemotherapeutic index of about 50.

In the Hygienic Laboratory method of Voegtlin and Smith the tests are likewise conducted with white rats and *Tr. equiperdum* but the infection is allowed to become heavier before treatment is given than in my method; consequently the amounts of arsphenamin required to effect sterilization are greater. Furthermore, in my method the trypanocidal dose is recorded as the smallest amount of compound effecting complete sterilization of the animal whereas in the Hygienic Laboratory method the minimal effective dose is the smallest amount ridding the blood of trypanosomes within twenty-four to forty-eight hours after administration as determined by microscopical examinations. Sometimes however, trypanosomes reappear and destroy the rat so that the minimal effective dose in the Hygienic Laboratory method is not necessarily the minimal curative dose in the meaning of my method. The two methods, however, are somewhat comparable in results, the minimal effective dose by the Hygienic Laboratory method being in general terms about 2.4 to 4 times larger than the minimal curative dose in my method.

In a study of the relative trypanocidal value of arsphenamin (salvarsan) of different manufacture by Voegtlin and Smith[17] the average minimal lethal dose was found to be 53.2 c.c. and the average minimal effective dose 3.1 c.c. per kilogram, both values being expressed in terms of cubic centimeters of 1:100 arsenic equivalent solution. These values are approximately equivalent to 0.116 gm. of arsphenamin per kilogram as the minimal lethal dose and 0.007 gm. per kilogram as the minimal effective dose giving a chemotherapeutic ratio of 17.

Trypanocidal Activity of Arsphenamin and Neoarsphenamin for the Guinea-Pig and Rabbit.—As described in Chapter X, trypanosomiasis in the guinea-pig and rabbit pursues a much different course than in the mouse and rat in that trypanosomes are found in the blood only during certain cyclic periods, the infection being essentially an involvement of the tissue and running a more chronic course. These features are especially characteristic of trypanosomiasis of the rabbit.

In order to determine the curative dose of arsphenamin and neoarsphenamin in these infections, it is necessary to keep the animals under observation for several months in order to make sure that relapses do not occur. For this reason trypanocidal tests employing guinea-pigs and rabbits are not as serviceable as tests employing rats for the routine testing of these compounds and very little use has been made of them; on the other hand, trypanosomiasis in these animals more closely approaches the course of syphilis in the human being by reason of the predominance of chronic tissue changes and the tests are of distinct service for gaining information on the trypanocidal activity of medicaments under these conditions.

The toxicity of arsphenamin and neoarsphenamin for guinea-pigs and rabbits by intravenous injection is not much different from that for rats when administered in exactly the same manner. The minimal trypanocidal doses for twenty-four hour infections is however, slightly higher for guinea-pigs and decidedly higher for rabbits, so that the chemotherapeutic indices are somewhat lower than observed in rat tests.

When the infection is allowed to continue in guinea-pigs for a week before treatment is given the minimal curative doses of both arsphenamin and neoarsphenamin are about 5 times more than required for twenty-four hour infections; these larger amounts are due to the greater difficulty of effecting sterilization of the tissues.

In the rabbit, the amount required to cure twenty-four hour infections is higher per body weight than required for similar infections of guinea-pigs and rats, but in the treatment of older infections (1 to 6 weeks) 2 to 3 times larger

doses are required to effect complete sterilization of the blood and fixed tissues.

Variation in Trypanocidal Activity and Keeping Qualities of Arsphenamin (Salvarsan).—From the chemical standpoint arsphenamin is quite a stable compound and when the powder is properly preserved, toxicity and trypanocidal activity remain constant to a remarkable degree over long periods of time. I have included one lot of arsphenamin in all trypanocidal tests of new compounds for almost a period of three years for purposes of comparison to express the trypanocidal action of new compounds in terms of the "arsphenamin index," ratio or coefficient, and the results have been quite uniform.

Different lots of arsphenamin prepared by the same manufacturer may vary to a slight degree in trypanocidal activity but marked variations are generally due to changes in the trypanosomes. In the manufacture of arsphenamin on a commercial scale the total output of a day is generally mixed into one large lot which tends to minimize slight variations in the toxicity and trypanocidal activity of individual lots. On several occasions I have laid aside a few ampules from time to time and after collecting these over periods of four or five months have tested all at the same time for trypanocidal activity; in this manner variations due to the trypanosomes were controlled and differences in trypanocidal activity ascribed to the compounds. In experiments of this kind the trypanocidal activity of arsphenamin has been found quite constant, an experiment conducted in 1919 with twelve different lots yielding minimal curative doses varying from 0.006 to 0.008 gm. per kilogram of body weight. In 1920–1921 a similar experiment yielded values varying from 0.003 to 0.005 gm. per kilogram and a third experiment 0.002 to 0.004 gm. per kilogram.

However, marked differences in trypanocidal activity are easily caused by variations in the resistance of the strain of trypanosomes. On at least four occasions during the past six years strains of *Tr. equiperdum* employed in my laboratory have been rendered arsenic resistant and whereas rats infected with normal strains were sterilized with doses of arsphenamin ranging from 0.002 to 0.004 gm. per kilogram, rats infected with the resistant strains required doses as high as 0.015 to 0.020 gm. per kilogram. On the other hand rats infected with normal strains taken from guinea-pigs or rabbits are likely to be sterilized with slightly smaller amounts than required for normal strains propagated in rats. I have, however, discussed these points in more detail in relation to the "arsphenamin index," but mention them here again to emphasize that apparent variations in the trypanocidal activity of arsphenamin may be more readily caused by variations in the resistance of the trypanosomes to the effects of arsphenamin than to the compound itself.

The arsphenamin (salvarsan) prepared in different laboratories yields approximately the same general average trypanocidal values.

In 1921, I again tested 20 different lots from six different laboratories including products prepared in Germany, Canada and the United States; the results showed the average minimal curative doses to range from 0.0018 to 0.0026 gm. per kilogram of rat. Kolle[18] has observed that in mice the maximum tolerated doses of salvarsan, silver, gold and platinum salvarsans have been from 0.1 to 02.5 gm. per kilo with minimal curative doses for *Tr. brucei* infections from 0.008 to 0.025 gm. per kilogram.

Toxicity and Trypanocidal Activity of Acid, Neutral and Alkalinized Solutions of Arsphenamin (Salvarsan).—Acid solutions of arsphenamin, that is, solutions of the dihydrochlorid in water without neutralization with sodium hydroxid, are from 4 to 6 times more toxic than solutions of the same compound after neutralization. Trypanocidal tests have shown that the

curative activity of acid solutions is likewise greater than neutralized and alkaline solutions, but the chemotherapeutic indices are lower; this is due to the striking influence of alkalinization upon toxicity for the animal host. The maximum tolerated dose of arsphenamin in acid solution is about 0.010 to 0.030 gm. per kilogram while the same compound in neutral (monosodium) or alkaline (disodium) solution is tolerated in doses of 0.120 to 0.150 gm. per kilogram. In other words, acid solutions are more toxic for both trypanosomes and test animal than neutral or solutions, but while the toxicity of arsphenamin in acid solution for the parasites is double that of the same compound in alkaline solution, the toxicity for the animal is 7 to 15 times higher.

Furthermore, it would appear that the chemotherapeutic indices of neutral (monosodium) solutions of arsphenamin are somewhat higher than alkaline (disodium) solutions. Adding about one third excess of sodium hydroxid to a neutral solution of arsphenamin and thereby converting it into an alkaline or disodium solution, may reduce toxicity for the trypanosomes (trypanocidal activity) to a greater degree than reduction of toxicity for the animal and thereby reduce the chemotherapeutic index of alkaline solutions. In one experiment conducted in 1919 the indices were as follows:

Acid solution	Maximum tolerated dose: 0.010–0.020 gm. Minimal curative dose: 0.003 gm.	= index of 3 to 6.
Neutral Solution	Maximum tolerated dose: 0.120–0.140 gm. Minimal curative dose: 0.003 gm.	= index 40 to 46.
Alkaline Solution	Maximum tolerated dose: 0.140–0.150 gm. Minimal curative dose: 0.004 gm.	= index 35 to 38.

In practice, however, alkaline solutions are to be preferred for intravenous injections in the treatment of syphilis, because they are somewhat safer and less likely to produce reactions.

Trypanocidal Activity of Shaken Solutions of Arsphenamin (Salvarsan).— It is a well-established fact that oxidation of arsphenamin increases the toxicity by conversion of a part of the drug into the more toxic amino-hydroxy-phenyl-arsenoxid (arsenoxid). This observation was early insisted upon by Ehrlich and his associates, who urged against unnecessary shaking of solutions of arsphenamin and upon the prompt administration of the drug after solutions were prepared to prevent the formation of this substance.

Schamberg, Raiziss and myself[19] have studied the effects upon trypanocidal activity of shaking acid and alkalinized solutions of arsphenamin marketed by three different laboratories. When 10 c.c. of 2 per cent. solutions in warm water were placed in 25 c.c. cylinders and shaken for one minute (about 250 times) followed by alkalinization in the usual manner and tested for trypanocidal activity, it was found that the solutions of some products sometimes sterilized rats in slightly smaller amounts than required of solutions that were not shaken beyond the time required for solution. However, when solutions were first alkalinized and then shaken for one and ten minute periods, trypanocidal activity was considerably increased.

Chemical examinations to determine quantitatively the oxygen requirements of the arsphenamins under these conditions on the basis that the trivalent arsenic takes up iodin quantitatively followed by oxidization to the corresponding arsonic acid derivative, have shown that when alkalinized solutions were shaken the oxygen requirement was decreased about 17.4 per cent. This indicated the production of arsenoxid which probably accounts for the solutions being rendered more trypanocidal by shaking. Voegtlin and Smith[20] believe that the therapeutic activity of arsphenamin is due to the formation of oxidation products in the body after injection, and the results of these experiments lends confirmation to these views. I will,

however, discuss this phase shortly in a consideration of the mechanism of trypanocidal activity of arsphenamin and neoarsphenamin.

Arsenoxid production, however, was not produced by shaking acid solutions of arsphenamin to as great degree as in alkalinized solutions and for this reason the shaking ordinarily required for the preparation of solutions of arsphenamin for administration in the treatment of syphilis does not materially influence either the toxicity or trypanocidal activity and particularly since the required shaking is done before alkalinization. Similar changes occurred with solutions of neoarsphenamin.

Trypanocidal Activity of Preserved Solutions of Arsphenamin; Influence of Standing upon Trypanocidal Activity.—Solutions of arsphenamin exposed to the air usually become darker in color and acquire an increased toxicity. These changes are likewise alleged to be due to oxidation and the prompt administration of the solutions has been insisted upon and emphasized. As a general rule the rapidity and degree of these changes is in proportion to the square surface of the solution exposed to the air, that is, they occur more rapidly in an Erlenmeyer flask than in a narrow cylinder. Solutions kept in an oxygen-free atmosphere undergo changes of this kind very slowly and toxicity may remain unaltered for relatively long periods of time. Changes in trypanocidal activity of alkalinized solutions of arsphenamin exposed to air are very peculiar. At first a slight increase of trypanocidal activity may occur followed by a marked decrease.

When alkalinized solutions are kept in cylinders filled to the stoppers, the color changes occurred much more slowly as likewise changes in trypanocidal activity; apparently retardation of these changes was due to the much smaller surface of the solutions exposed to air.

Alkalinized solutions of arsphenamin kept in high vacuum do not usually show any color changes or increase of toxicity for periods of several months and indeed, for a year or more in some instances. *A gradual reduction in trypanocidal activity,* however, may take place and for this reason preserved solutions of arsphenamin should not be kept indefinitely when employed for the treatment of syphilis. On the basis of this gradual loss of trypanocidal activity, which is parallel with loss of spirocheticidal properties, the Hygienic laboratory requires that such solutions shall not be older than six months when employed in the treatment of syphilis.

We have found similar changes in trypanocidal activity with solutions of neoarsphenamin, described later in this chapter. Whether or not the physical changes in these solutions embracing a darkening in color with the formation of precipitates and increase of toxicity are due to the formation of arsenoxid, cannot be definitely stated although under the circumstances one naturally surmises that oxidation products are responsible. As discussed in Chapter XLVI, the toxicity of these solutions may not be increased or an increase of toxicity may be followed by a decrease suggesting in some instance the gradual production of the pentavalent amino-hydroxy-phenyl arsonic acid. The same is sometimes true of solutions kept in contact with air, that is, a slight increase of trypanocidal activity may be detected followed by a progressive decrease.

Trypanocidal Activity of Solutions of Arsphenamin (Salvarsan) Prepared with Water at Varying Temperatures.—Of further interest in this connection is the influence upon trypanocidal activity of the temperature of the water employed for preparing solutions of arsphenamin. Ordinarily water at room temperature (approximately 22°C.) is employed, but higher temperatures may be required in order to effect complete solution of the powder with a minimum degree of shaking.

I have conducted trypanocidal tests with the arsphenamins prepared by three different laboratories by preparing three solutions of each with water at 20°–22°C., 70°C. and 100°C. After alkalinization in the usual manner these were injected into infected rats according to the technic of my trypanocidal tests; the results have shown that the arsphenamin prepared by two laboratories tended to loose slightly in trypanocidal activity when boiling water (100°C.) was employed in preparing the solutions; ordinary hot water (70°C.) had no appreciable effect. With the arsphenamin prepared in a third laboratory, which was slowly soluble in cold water, the use of hot and boiling water had no effect upon trypanocidal activity. Why these varying results occurred with the arsphenamins of different manufacture I am unable to state; as discussed in Chapter XLVI, solutions prepared with water at 70°C. and 100°C. were almost always less toxic than solutions prepared with water at 22°C. indicating that heat tends to reduce the toxicity of arsphenamin for both host (the test animal) and parasites (*Tr. equiperdum*).

Toxicity and Trypanocidal Activity of Sodium Arsphenamin (Sodium Salvarsan).—Since the disodium salt of arsphenamin, prepared by alkalinizing solutions with sodium hydroxid, does not keep well and requires almost immediate administration, Ehrlich prepared a stable sodium salt known as "1206" in his series and possessing a chemical structure essentially the same as arsphenamin.

The substance when dissolved in water yields a neutral or slightly alkaline solution ready for administration. It has been extensively employed in Europe and to a lesser extent in this country, for the treatment of syphilis although extensive studies of its curative activity for experimental infections do not appear to have been made.

Schamberg, Raiziss and myself[21] have studied the toxicity and trypanocidal activity of the sodium arsphenamin prepared by two different laboratories. The toxicity of four different lots from one of these laboratories varied from 0.190 to 0.250 gm. per kilo with an average of 0.212 gm.; the minimal curative doses for *Tr. equiperdum* infections varied from 0.020 to 0.030 gm. per kilo with an average of 0.024 gm. and yielding a chemotherapeutic index of 8.8.

The toxicity of eight different lots from a second laboratory likewise varied from 0.190 to 0.250 gm. per kilo with an average of 0.215 gm.; the minimal curative doses varied from 0.010 to 0.020 gm. with an average of 0.016 gm. and yielding a chemotherapeutic index of 13.4.

At the time these tests were made the average minimal curative dose of arsphenamin was 0.005 gm. per kilo and neoarsphenamin about 0.009 gm. Sodium arsphenamin, therefore, was from 3 to 5 times less trypanocidal than arsphenamin and 2 to 3 times less trypanocidal than neoarsphenamin. Since neoarsphenamin is less toxic, more trypanocidal and just as easy of administration as sodium arsphenamin, the former has been more extensively employed in the treatment of syphilis.

Toxicity and Trypanocidal Activity of Phospharsphenamin (Galyl).—This substance, which is manufactured in France and employed in the treatment of syphilis especially by French clinicians, is said to be an arsphenamin derivative containing phosphorous, 4.4′ dihydroxyarsenobenzene 3.3′ phosphamic acid or No. 1116 of Mouneyrat's series. In the United States it is licensed under the official name of "phospharsphenamin," its trade name being "galyl."

Phospharsphenamin is supposed to contain 35.3 per cent. arsenic and 7.5 per cent. phosphorus. It occurs as an acidic substance, insoluble in water, and dissolves in aqueous sodium carbonate. It is dispensed sealed up in

ampules containing the dry sodium carbonate, so that it readily dissolves upon the addition of water. Solutions made in this way are yellow, or greenish yellow, the greenish color rapidly deepening upon standing.

A new "galyl" has been recently distributed which does not require alkalization. A study of this substance by the chemical laboratory of the American Medical Association in 1922 showed that it responds to practically all the tests for sodium arsphenamin except that there is present both sulphite and phosphate. The Council on Pharmacy and Chemistry concluded that when the new galyl is dissolved in water, either it is partly decomposed into phosphate and sodium arsphenamin or else the original product contains sodium arsphenamin and sodium phosphate. In either case the injection will probably amount to the administration of a mixture of phospharsphenamin (if any is present), sodium arsphenamin, sodium phosphate, sodium sulphite and sugar.

In my laboratory the average maximum tolerated dose of phospharsphenamin (galyl) for white rats by intravenous injection was about 0.350 gm. per kilogram of body weight; the minimal curative dose for twenty-four-hour *Tr. equiperdum* infections was 0.085 gm. per kilo giving a chemotherapeutic index of 4.1. According to Kolle[22] the maximum tolerated dose of galyl for mice is 0.500 gm. per kilo and the minimal curative dose for *Tr. brucei* infections about 0.165 gm. per kilo giving a chemotherapeutic index of 3.

Toxicity and Trypanocidal Activity of Silver Sodium Arsphenamin (Silver Salvarsan).—In 1912 Ehrlich and his associates succeeded in synthesizing a new series of compounds in which different molecular proportions of the salts of heavy metals enter into intimate combination wtih the arsenobenzol compounds. A short time afterward, Danysz,[23] working independently, announced the discovery of metallic complexes from arsphenamin and silver nitrate and since then, silver sodium arsphenamin or silver salvarsan, as it is commonly designated, has been widely employed in the treatment of syphilis.

In 1915 Ehrlich and Karrer[24] published more details concerning aromatic compounds of trivalent arsenic combined with complex salts of heavy metals which were characterized by deep colors and great stability. These observations included all arseno compounds, as well as arsenoxids and arsines under certain conditions, and all salts of copper, silver, gold, mercury, palladium, platinum, iridium, ruthenium, and osmium. According to Ehrlich and Karrer the metal may be bound by the orthoamino phenol group, by both the phenol and arseno groups, or the residual affinity of the arsenic group may contain the metal; however, the silver product described by them in 1915 is not of the same composition as the silver sodium arsphenamin now employed in the treatment of syphilis. The exact chemical composition of this substance is unknown but it is regarded by Myers[25] as the sodium salt of the monosilver 3-3′ diamino—4—4′ dioxy-arseno-benzene.

According to Kolle,[26] who has extensively studied the biological properties, silver arsphenamin should contain 22.4 per cent. arsenic and 14.1 per cent. silver; analyses show, however, that the arsenic content may vary from 19 to 21.5 per cent. and the silver from 13.8 to 15.7 per cent.

The toxicity of the compound ranges from 0.090 to 0.120 gm. per kilogram of rat by intravenous injection in the usual standard method, and in the United States, the Hygienic Laboratory requires that products for use in the treatment of syphilis shall be borne by rats in a minimum dose of 0.120 gm. per kilogram.

I have determined the minimal curative dose of different lots of silver sodium arsphenamin prepared in two different laboratories during 1920 and

1921; the average minimal curative dose was approximately 0.0028 gm. per kilo as compared with 0.004 of arsphenamin. In 1922, however, the trypanocidal activity of silver sodium salvarsan was found to be about 0.002 gm. per kilo and arsphenamin approximately 0.003 gm. Inasmuch as the toxicity of this arsphenamin was about 0.120 gm. per kilo of rat and the acceptable lots of silver sodium arsphenamin about 0.110 gm., the chemotherapeutic index of the silver compounds was 55, as compared with 40 for the index of arsphenamin.

According to Kolle[27] the maximum tolerated dose of silver arsphenamin (silver salvarsan) for mice is about 0.250 gm. per kilo and the minimal curative dose for *Tr. brucei* infections about 0.011 gm. per kilo giving a chemotherapeutic index of 22.

Toxicity and Trypanocidal Activity of Sulfarsenol (Sulpharsphenamin).— Within the past few years another organic arsenical has been introduced for the treatment of syphilis designated as *sulfarsenol*. Ehrlich and his associates in 1912 described a compound with the substitution of an amino radical of arsphenamin by a methylene sulphonic acid group and the compound "sulfarsenol" prepared by Lehnhoff-Wyld appears to be identical in structure. In 1922, Voegtlin, Johnson and Dyer[28] prepared the same compound, but differing from the German method in that they begin with arsphenamin in a water-alcohol solution, work at ordinary temperature and precipitate the final disodium salt with alcohol in one continuous operation, for which they proposed the name *sulpharsphenamin*. Both names therefore, apparently designate the same compound which occurs as a light, yellowish power freely soluble in cold water. Unlike arsphenamin and neoarsphenamin, when injected intramuscularly, it has been found to produce but slight local irritant properties and has been established as a remedy of choice in the treatment of syphilis when subcutaneous or intramuscular injections are indicated.

The arsenic occurs in from 20.7 to 23.6 per cent. and sulphur in from 8.7 to 12.8 per cent., the atomic ratio of arsenic to sulphur ranging from 1:0.91 to 1:1.45. The compound differs from neoarsphenamin by the presence of one additional atom of oxygen.

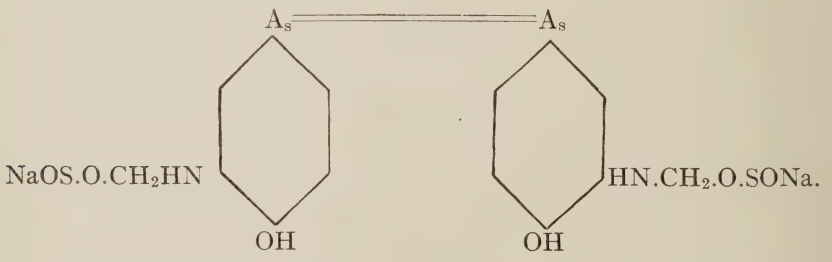
Levy-Bing, Lehnhoff-Wyld and Gerbay[29] gave 0.400 gm. per kilo as the maximum tolerated dose for mice; they do not appear to have made trypanocidal tests. According to Voegtlin, Johnson and Dyer the toxicity of sulpharsphenamin for white rats by intravenous injection was approximately 0.395 gm. per kilo and by subcutaneous injection approximately 0.530 gm. The minimal effective dose as determined by the Hygienic Laboratory method with rats infected with *Tr. equiperdum* was approximately 0.021 gm. per kilo when administered intravenously and 0.024 gm. by subcutaneous injection. As shown by these investigators, the full effects of sulpharsphenamin may require 3 or 4 days whereas both arsphenamin and neoarsphenamin act in 1 to 2 days. This slower action on the part of sulpharsphenamin, which is probably due to a slower rate of oxidation in the body to the trivalent arsenious oxid compounds, may constitute however, a desirable feature of the drug in the treatment of some cases of syphilis when slow but prolonged therapeutic activity is indicated. According to Myers and Corbitt[30] sulpharsphenamin by intravenous injection to rats is at least two and a half times less trypanocidal than good brands of neoarsphenamin. Raiziss, Severac and Moetsch[31] employing the Voegtlin trypanocidal method, found the minimal effective dose to be about 18 mgm. per kilogram as compared with 4 mgm. of arsphenamin or 6 mgm. of neoarsphenamin; practically the same results were observed by both intramuscular and intravenous routes of administration.

In my laboratory the average maximum tolerated dose of sulpharsphenamin kindly furnished by Dr. Voegtlin was 0.310 gm. per kilo when administered to rats intravenously and 0.400 gm. per kilo by subcutaneous injection. The minimal curative dose in *Tr. equiperdum* infections by intravenous injection according to my method was 0.020 gm. per kilo of rat and 0.015 gm. per kilo by subcutaneous injection. Sulpharsphenamin prepared by a second laboratory showed a maximum tolerated dose of 0.450 gm. per kilo intravenously and 0.600 gm. by subcutaneous injection; the minimal curative dose by subcutaneous injection was 0.010 gm. per kilo and 0.030 gm. intravenously showing that sulpharsphenamin is least toxic and more trypanocidal by subcutaneous than by intravenous injection.

It was observed that when sulpharsphenamin was administered intravenously that its chemotherapeutic index was equal to or but slightly less than the index for arsphenamin by intravenous injection; the index for sulpharsphenamin was however, much less than that of neoarsphenamin by this route of administration.

However, when sulpharsphenamin is given subcutaneously the chemotherapeutic index is increased, because its toxicity is lower while its trypanocidal activity is increased by this route of administration. These effects are probably due to the greater facility for oxidation in the tissues with the production of therapeutically active "oxids" and indicates quite clearly that the maximum degree of curative activity of sulpharsphenamin is to be gained by administering the compound by subcutaneous or intramuscular injection.

Toxicity and Trypanocidal Activity of Neoarsphenamin (Neosalvarsan).—Impressed with the dangers attending the accidental administration of acid solutions of arsphenamin and desirous of simplifying the administration by evolving a substance that does not require neutralization before injection, Ehrlich continued his investigations with the arsenobenzol compounds and finally discovered a new compound sodium 3,3′—diamino-4,4′-dihydroxy-arseno-benzene—N—methylene sulphinate, designated as "neosalvarsan" or "914." This substance is now known officially in the United States as "neoarsphenamin" and while the exact formula is unknown, the following structure is generally assigned:



Since neoarsphenamin contains on the average 19 per cent. arsenic as compared with arsphenamin which contains approximately 30 per cent., the curative activity of the former is less; according to Ehrlich and Hata the ratio of therapeutic activity is such that 0.6 gm. of arsphenamin is equivalent to 0.9 gm. of neoarsphenamin as based upon therapeutic experiments on hen spirillosis and mice infected with the spirochetes of relapsing fever.

In 1919, Schamberg, Raiziss and myself[32] determined the trypanocidal activity of neoarsphenamin prepared by six different laboratories including the German product. The general average trypanocidal dose for all com-

pounds was 0.004 gm. per kilogram of rat, neoarsphenamin being therefore, about 1.7 times less trypanocidal than arsphenamin. Under these conditions the equivalent of 0.6 gm. of arsphenamin is 1.05 gm. neoarsphenamin in the treatment of experimental trypanosomiasis.

During 1920–1921, however, the trypanocidal activity of one of the American-made products was increased and not infrequently proved almost as trypanocidal as arsphenamin.

Similar results were observed by Voegtlin and Smith[33] in a comparative study of the neoarsphenamins prepared in different laboratories, insofar as concerns the ratio of trypanocidal activity between arsphenamin and neoarsphenamin. The general average of trypanocidal activity was 3.4 c.c. of 1:100 arsenic equivalent solution per kilogram of rat; with the arsenic content at 18.9 per cent. this amount was equivalent to about 0.0079 gm. neoarsphenamin per kilogram, which is larger than required in my test because of the larger number of organisms requiring destruction. The ratio of trypanocidal activity, however, between arsphenamin and neoarsphenamin was 0.6:1.02 gm. which was quite similar to that found by Schamberg, Raiziss and myself.

In a study of the trypanocidal activity of German and English-made neoarsphenamins by Dale and White, assisted by Burn, Dushan and Marchal,[34] the minimal curative doses in 72-hour periods of observation varied from 0.015 to 0.020 gm. per kilogram of mouse with a general average of 0.020 gm. The general average for arsphenamin was 0.010 gm. per kilogram so that the ratio of trypanocidal activity was 0.6:1.2 gm. being slightly higher than observed by Voegtlin and Smith and myself.

Variations in Trypanocidal Activity of Neoarsphenamin (Neosalvarsan).— From the chemical standpoint neoarsphenamin is a more unstable compound than arsphenamin. Different lots prepared by the same manufacturer are more apt to vary in the biological properties of toxicity and trypanocidal activity than arsphenamin; the drug is likewise more likely to deteriorate in the ampules than arsphenamin.

On several occasions I have tested lots of twelve different samples of neoarsphenamin at one time in order to equalize the variations due to the organism and have found that the trypanocidal activity may vary all the way from minimal curative doses of 0.001 gm. to 0.010 gm. per kilogram of body weight although the great majority of products fell within the limits of 0.002 to 0.004 gm. per kilogram of rat.

Voegtlin and Smith in the Hygienic Laboratory have also found wide variations in the minimal effective doses of the neoarsphenamin of different manufacture and have called particular attention to this fact in relation to the use of neoarsphenamin in the treatment of syphilis, to which I will refer later in more detail. These investigators found that the trypanocidal activity of neoarsphenamin of different manufacture may vary from 2.5 to 4.0 c.c. of 1:100 arsenic equivalent solution per kilogram of rat equivalent approximately to 0.005 to 0.010 gm. neoarsphenamin per kilo, with an average of 3.4 c.c. of 1:100 arsenic equivalent solution or about 0.007 to 0.008 gm. neoarsphenamin per kilo.

Dale and White report that the British-made neoarsphenamin had at first a minimal curative dose of 0.040 to 0.050 gm. per kilogram of mouse which later the manufacturers improved upon to the extent that the dose became 0.010 to 0.020 gm. per kilogram.

According to Kolle,[35] the maximum tolerated dose of neoarsphenamin (neosalvarsan) is about 0.375 gm. per kilo and the minimal curative dose for mice infected with *Tr. brucei* about 0.040 gm. per kilo giving a chemotherapeutic index of 9.

Keeping Qualities of Neoarsphenamin.—As previously stated the powder sealed in ampules from which the air has been excluded either by the production of a vacuum or by displacement of the air with a monoxidizing gas such as carbon dioxid, nitrogen, or hydrogen, tends to hinder physical and biological changes. Roth[36] has reported that a study of neoarsphenamin prepared by four different laboratories showed that changes may occur in color, solubility, toxicity, mobility in ampule, and odor after varying periods up to three years.

I have also studied the question of changes in trypanocidal activity and toxicity by testing the same product of three different laboratories at intervals of a month over a period of one year, the first tests being conducted in from three to four weeks after the manufacture of the respective products. Each lot was kept at room temperature and tested against the same strain of *Tr. equiperdum.* At the same time observations were made on the toxicity and such physical changes as alterations in color of the solutions, solubility, odor, etc. During this period no changes in solubility, color or odor occurred with any of the compounds; it was also noted that changes in trypanocidal activity did not occur in nearly the same degree as changes in toxicity. A slight tendency to deterioration in trypanocidal activity was apparent over this period of one year but the changes were neglible and within the range of experimental error.

Trypanocidal Activity of Shaken and Preserved Solutions of Neoarsphenamin (Neosalvarsan).—Neoarsphenamin is ordinarily so readily soluble in water that the influence of shaking the solution does not enter as a possible factor influencing its toxicity and trypanocidal activity. However, some products are not as readily soluble as others and may require considerable shaking which, under certain circumstances, may result in physical and biological changes.

The influence upon toxicity of shaking solutions of neoarsphenamin in water, is discussed in Chapter XLVI. Schamberg, Raiziss and myself[37] have also studied the effects upon trypanocidal activity with practically negative results. Two per cent. solutions in water shaken vigorously for one minute (10 c.c. in a 25 c.c. cylinder for approximately 250 times) did not reduce or increase trypanocidal activity; when shaken for ten minutes the trypanocidal activity of the products of two laboratories was very slightly decreased, as shown by the late development of trypanosomiasis.

When solutions of neoarsphenamin in water are kept at room temperature a loss in trypanocidal activity occurs, as is true of solutions of arsphenamin. The degree and rapidity of this loss in curative activity is proportional to the square surface of exposure to air and more rapid than in the case of arsphenamin. Inasmuch as there is no practical end to be served by the preservation of solutions of neoarsphenamin over long periods of time in view of the ease of preparing fresh solutions as required, I have never conducted similar studies with solutions preserved in high vacuum as have been described with solutions of arsphenamin; I surmise, however, that similar changes would be observed in the nature of a gradual decrease in trypanocidal activity after the elapse of several months.

Trypanocidal Activity of Solutions of Neoarsphenamin (Neosalvarsan) Prepared with Water at Varying Temperatures.—Of more practical importance is the influence upon trypanocidal activity that may be exerted by the temperature of the water employed for preparing solutions of neoarsphenamin for administration in the treatment of syphilis. Ordinarily water at room temperature (about 22°C.) is employed owing to the readily soluble nature of the compound.

The results of comparative trypanocidal tests with the neoarsphenamin prepared by three different laboratories, each tested at the same time dissolved in water at 22°C., 70°C. and 100°C. have shown that boiling water tends to slightly reduce the trypanocidal activity of most samples, while ordinary hot water (70°C.) has no appreciable effects.

Rapidity of Trypanocidal Activity of Arsphenamin and Neoarsphenamin. As shown by Voegtlin and Smith, the intravenous injection of minimal curative doses of arsphenamin and neoarsphenamin is followed almost at once by a decrease of the number of parasites in the blood until in from four to six hours and almost certainly within twenty-four hours after injection, none are to be found in the peripheral blood. According to these investigators this immediate trypanocidal action is especially characteristic of arsenicals belonging to the arsenoxid group, that is, trivalent compounds capable of being rapdily oxidized in the body.

I have likewise observed essentially similar results. Both arsphenamin and neoarsphenamin produced an agglutination of the organisms in the blood, which interfered with the accuracy of the counts. With the larger doses this phenomenon did not occur but rapid reduction in the numbers of parasites was produced resulting in sterilization in about six hours after injection. I have not seen any reference in the literature to the agglutination of trypanosomes by sub-curative doses of arsphenamin and neoarsphenamin and it is highly probable that the phenomemon is part of the mechanism concerned in the trypanocidal activity of these compounds.

Trypanocidal Activity of Mutiple Doses of Arsphenamin and Neoarsphenamin.—In the treatment of syphilis in its early stages, arsphenamin and neoarsphenamin are administered after various plans of treatment. The medicaments may be given once a week, twice a week, daily for three doses or daily for six doses, etc., and each plan has been endorsed by various physicians so that great confusion exists regarding the best course to pursue. A large number of factors require consideration among which may be mentioned the questions of toxicity, the stage of the disease, the route of administration, the rate of absorption and elimination of the medicament and the rapidity with which the compound is rendered therapeutically active in the body after administration, granting that Voegtlin and Smith are correct in their belief that arsphenamin and neoarsphenamin are not of themselves trypanocidal or spirocheticidal but first require oxidation in the body.

In order to obtain more information on this subject I have infected rats with 500,000 *Tr. equiperdum* by intraperitoneal injection and then subjected them to treatment after various plans, beginning 24 hours after inoculation. Similar experiments have been conducted with rabbits infected with *Spirochaeta pallida*, which will be described in Chapter XXIII. These experiments have shown that considerably higher trypanocidal activity of arsphenamin over neoarsphenamin in trypanosomiasis of the rat when treatment is given in fractions of the single minimal curative dose of each compound; also the advantage of daily treatment with small doses over the one week plan with large doses. The significance of these results in relation to the treatment of syphilis will be discussed in Chapter XXIX.

Toxicity and Trypanocidal Activity of Tryparsamid.—One of the most interesting and highly trypanocidal of the pentavalent arsenical compounds is the sodium salt of N-phenylglycineamid-p-arsonic acid, prepared by Jacobs and Heidelberger[38] in 1919, during the course of the synthesis of new types of arsenic compounds for the treatment of experimental trypanosome and spirochete infections. They were lead to work with the pentavalent arsenicals as presented by the arsonic acids, because of the opportunity

afforded for a study of the relationship between chemical structure and biological action and because such compounds offered the advantage of forming soluble and stable salts and fewer of the preparative uncertainties that have been associated with the usual arseno trivalent compounds.

Phenylglycin-p-arsonic acid, and its homologue, O-methylphenylglycin-p-arsonic acid had been previously described in a German patent and served as a source of the arsenophenyl glycins by reduction; by new methods Jacobs and Heidelberger rendered possible the preparation of a new series of aromatic arsenic compounds in which the free carboxyl group of the glycins was changed to the amid or substituted amid group. N-phenylglycineamid-p-arsonic acid readily yields a colorless, crystalline sodium salt called "tryparsamid" which is extremely soluble in water and forms neutral solutions which are perfectly stable. Brown and Pearce[39] have thoroughly studied the toxicity, trypanocidal and spirocheticidal properties of the sodium salt. In the trypanocidal tests strains of *Tr. brucei*, *Tr. gambiensi*, *Tr. equinum*, *Tr. equiperdum* and *Tr. evansi* were employed in mice, rats, guinea-pigs and rabbits. As a general rule the mice and rats were treated about eighteen to twenty-four hours after infection, guinea-pigs about one week and rabbits about ten to fifteen days after infection, when trypanosomes had been demonstrated in the peripheral blood; the treated animals were kept under observation from one to three months. The results have shown that the different species of trypanosomes varied considerably in their resistance to tryparsamid; the species of animal also had some influence upon the results. The curative dose of 0.2 to 0.3 gm. per kilo of body weight was quite constant for *Tr. brucei*, *Tr. gambiense*, and *Tr. equinum* infections in mice and *Tr. bruce* and *Tr. gambiensi* infections in rats, but with *Tr. equiperdum* and *Tr. evansi* infections in mice, the dose required to effect a cure was considerably higher. The highest dose used, 0.5 gm. failed to cure all mice infected with *Tr. equiperdum*, although there were cures at doses as low as 0.225 and 0.25 gm. With infections of *Tr. evansi*, mice treated with 0.75 gm. did not relapse, but below this dose, cures were uncertain. Both these infections however, were more easily handled in rats than in mice, since there were no relapses with doses of 0.4 gm. in *Tr. equiperdum* and none with 0.3 gm. in *Tr. evansi* infections.

In my tests with *Tr. equiperdum* infections of rats the minimal curative dose of tryparsamid was 0.200 gm. per kilo by intravenous injection; the maximal tolerated dose was 1.0 gm. per kilo. These results have yielded, therefore, the following chemotherapeutic index:

$$\frac{\text{Maximum tolerated dose: 1.0 gm. intravenously}}{\text{Minimal curative dose: 0.2 gm. intravenously}} = 5$$

With the Hygienic Laboratory method of Voegtlin and Smith, I found the minimal effective dose for rats to be 0.3 gm. per kilo and the chemotherapeutic index as follows:

$$\frac{\text{Maximum tolerated dose: 1.0 gm. intravenously}}{\text{Minimal effective dose: 0.3 gm. intravenously}} = 3.3$$

The rapidity of the trypanocidal action of tryparsamid in trypanosomiasis of mice, rats and guinea-pigs is quite marked, the peripheral blood being cleared of organisms in eighteen to twenty-four hours after the treatment of twenty-four hour infections. With rabbits treated after clinical signs of the diseases had been established, a system of repeated dose therapy has been employed by Brown and Pearce with advantage in the treatment of both initial and relapsed infections, especially in those cases in which there is

induration or even necrosis of tissues with weakness and emaciation of the rabbit. The factor of time of repetition or the spacing of doses was in their experience as important as that of size of the dose employed and depends upon the rate, degree, and duration of action of the particular dose of the drug in question. Tryparsamid apparently possesses the power of tissue penetration to a marked degree and the repetition of small doses, such as 0.15 gm. per kilo of body weight on successive or alternate days, has given successful results as regards both the immediate regression and healing of lesions and ultimate permanent cures in severe, chronic infections. In *Tr. brucei* infections intramuscular injections of single or repeated doses yielded practically the same effects as by intravenous injection, while the effects were somewhat slower after subcutaneous injections.

Toxicity and Trypanocidal Activity of Other Organic Compounds of Arsenic.—The results of toxicity and trypanocidal tests with various other trivalent and pentavalent compounds of arsenic including those already discussed, are summarized in Tables 1 and 2. Some of these compounds are of special interest by reason of being intermediate compounds in the preparation of arsphenamin (salvarsan) as the pentavalent compounds atoxyl, the monosodium salt of 4-hydroxyphenylarsonic acid and the sodium salt of 3-nitro-4-hydroxyphenylarsonic acid. The "oxids" of the trivalent arseno compounds are likewise of special interest in relation to the theory of Voegtlin and Smith that the trypanocidal activity of this class of arsenical compounds depends upon oxidation processes in the body.

It is true that the results observed by different investigators with presumably the same compounds have varied, but in this connection it is to be remembered that the results vary considerably according to the technic employed for trypanocidal tests; furthermore, the chemical constitution of many of these substances is so complicated and the methods for their preparation so apt to vary in some detail in different laboratories, that the results should be accepted and evaluated only in broad and general manner.

Mechanism of Trypanocidal Activity of Arsenical Compounds.—Since atoxyl is practically without trypanocidal activity in the test tube Ehrlich has maintained that it must be reduced from its comparatively inactive in pentavalent form to the more active trivalent form before parasiticidal effects become apparent. Breinl and Nierenstein[40] stated in 1909 that in their opinion atoxyl when administered first combined with the serum proteins by means of the amino group, followed by a process of oxidation of the benzene nucleus by means of oxidases from the tissues as well as probably from the trypanosomes themselves with the liberation of arsenic. At the same time a process of reduction takes place by which atoxyl is split into arsenious acid and anilin, the latter being eliminated in the feces. The arsenic liberated by this dual process of oxidation and reduction is regarded as being actively trypanocidal in its nascent state. Later Nierenstein[41] modified this theory somewhat to state that not only was arsenic rendered trypanocidal in this manner, but that the amino group in atoxyl as well as in certain dyes, was directly trypanocidal.

Levaditi's "Trypanotoxyl" Theory.—Levaditi[42] has stated that atoxyl is not primarily trypanocidal *in vivo* but first unites with substances in the liver with the production of a trypanocidal substance designated as "trypanotoxyl." In other words it would appear that the trypanocidal and probably the spirocheticidal activity of the organic arsenical preparations *in vivo* is not a direct and simple chemical action of these substances upon the parasites but that a change occurs in the blood and other tissues. This change may be: (a) the formation of new combination compounds presumably with the

TABLE 1.—TOXICITY AND TRYPANOCIDAL ACTIVITY OF TRIVALENT ORGANIC ARSENICAL COMPOUNDS

SODIUM SALTS OF	PER CENT. ARSENIC	TEST ANIMAL	ROUTE OF ADMINISTRATION	TOXICITY PER KILO		TRYPANOCIDAL TESTS

proteins; (b) a simple chemical change of oxidation or reduction without the formation of a combination product; (c) a production of antibodies, or (d) a combination of one or more of these factors.

The liver cells however, do not appear in my experiments to increase the trypanocidal activity or toxicity of arsphenamin to a greater extent than physiological saline solutions. I have prepared 2 per cent. alkalinized solutions of arsphenamin in 20 per cent. suspensions of very finely divided rabbit liver and after placing them in an incubator for an hour have determined the toxicity and trypanocidal activity at the same time similar solutions of the same products were prepared in saline solutions and incubated one hour before injection; solutions were likewise tested immediately after preparation. The solutions in saline solution and liver emulsion after standing one hour in an incubator were usually, but not always, slightly more toxic and more trypanocidal than freshly prepared solutions. As a general rule however, the liver cell solutions were slightly less toxic than the saline solution preparations although the trypanocidal properties were about equal. These effects were ascribed to the production of oxidation products of arsphenamin as the result of standing in an incubator for an hour before injection. It is possible that enzymes from the liver cells may hasten the process, but there were no evidences of the formation of therapeutically active combination compounds of the arsphenamin and cellular substances.

We have already noted that solutions of arsphenamin and neoarsphenamin exposed to air acquire increased trypanocidal activity presumably by the formation of oxids. In this connection it may be recalled that Swift and Ellis found that heating serum taken from blood drawn within an hour after the intravenous injection of arsphenamin, increased its spirocheticidal properties probably by the same process. A question of importance is whether this change is brought about more rapidly in serum or emulsions of organs and particularly of the liver, than in water or saline solution. I have conducted experiments along these lines which tend to show that the menstrum has but slight influence upon the process. Leaving the solutions stand for 2 hours at room temperature increased the rate of trypanocidal activity but as stated above, the trypanocidal activities of the solutions in saline solution were about the same as solutions in rat serum, blood and suspensions of liver, spleen and brain. In other words, a chemical change had occurred tending to increase trypanocidal activity, but this was not appreciably influenced by the menstrum.

Voegtlin and Smith's Oxidation and Reduction Theory.—It is clearly established that trivalent compounds of arsenic are more toxic and likewise more trypanoicidal than pentavalent compounds. The same is true of compounds of antimony and some other metals. As shown by the work of Voegtlin and Smith the time required for the appearance of toxic symptoms or evidences of trypanocidal activity is generally longer for pentavalent than for trivalent arsenical compounds and since Binz and Schultz (1879) and others have shown tha tarsenic is reduced in the body, it is reasonable to assume that the longer latent period required by the pentavalent compounds is for the reduction of a sufficient amount of the drug to the trivalent form.

Voegtlin and Smith have furthermore shown that compounds containing arsenic in the "oxid" form (R.As = O) exert toxic and trypanocidal effects much more rapidly than arsenobenzol compounds. Their method is splendidly adapted for such studies on the rate of disappearance of trypanosomes from the blood and with it they have clearly demonstrated that after the intravenous injection of the minimal effective dose of a compound belonging to the arsenoxid group, the number of trypanosomes at once decrease until

all have been killed, requiring ten to sixty minutes, depending on the size of the infection. The immediate onset of the reaction and the great regularity by which it proceeds, shows in their opinion, that the compounds of the arsenoxid type are directly trypanocidal.

On the other hand according to the experiments of Voegtlin and Smith, the injection of twice or even several times the minimal effective dose of the arsenobenzol derivatives and the pentavalent arsenicals does not produce material trypanocidal effects for a period of one to six hours and in their opinion, these compounds are not themselves trypanocidal, but must be first converted into the active "oxids," the oxidation in the case of the arsenobenzol derivatives being as follows:

$$R.As = As.R \rightarrow R.As = O.$$

If this view is correct and I believe that Voegtlin and Smith have made out a strong case for it although Schumacher[42a] has recently advanced the hypothesis that arsphenamin destroys spirochetes by abstracting oxygen from them in the tissues, arsphenamin and neoarsphenamin are not themselves trypanocidal but first require oxidation in the body to the therapeutically active "oxids." Of course in the preparation of the solutions sufficient oxids may be produced or be present in the powder, to exert some immediate effects, but their demonstration of the latent period following the injection of arsenicals belonging to the arsenobenzol group and pentavalent compounds before the main trypanocidal effects are apparent, naturally leads to the conclusion that some change is required in the body and it is natural to surmise that the oxids are important since the first logical step in oxidation would be the breaking down of the arseno-grouping to the oxid grouping. In addition to their own experiments Voegtlin and Smith draw attention to other facts in support of their theory. For example, the greater toxicity and trypanocidal activity of solutions of arsphenamin and neoarsphenamin kept in contact with air is attributed to the effects of oxidation. As first shown by Ehrlich and his associates, this leads to the production of para-oxy-m-amino-phenyl-arsenoxid which is seven to ten times more toxic than arsphenamin and neoarsphenamin and likewise more trypanocidal; furthermore, as shown by Voegtlin and Smith it exerts a direct action on the parasites as indicated by the absence of a latent period after intravenous injection. In our own experiments, previously discussed, solutions of arsphenamin and neoarsphenamin, shaken in air or left in contact with air, also showed a tendency for becoming more toxic and more trypanocidal unless the process of oxidation was greatly prolonged when a decrease of toxicity and trypanocidal activity followed apparently due to the formation of the pentavalent amino-hydroxy-phenyl arsonic acid, first produced by Ehrlich and Bertheim in 1912 by oxidizing arsphenamin in alkaline solution by means of hydrogen peroxid.

The fact that arsphenamin and neoarsphenamin are less trypanocidal and spirocheticidal in the test tube than in the living body is also interpreted as evidence in favor of this theory of oxidation. Likewise observations showing that pentavalent arsenical and antimonial compounds are relatively inert for bacteria, yeast and protozoa *in vitro*. As previously stated Ehrlich advanced the theory that the pentavalent arsenicals must be reduced in the body before becoming therapeutically active, but reduction also leads to the same As:O-grouping as is formed on the oxidation of the arsenobenzol grouping. Since, however, reduction is probably less easily accomplished than oxidation of the arsenobenzols, it may be expected that the latent period would be longer before trypanocidal effects would be apparent after intravenous injection, and this has actually been found the case by Voegtlin and Smith. By

reason of this longer latent period these investigators have very properly pointed out that the dose of those compounds which undergo reduction before becoming therapeutically active must be larger than those readily reduced and oxidized, because while these processes are going on, a certain amount of the compound is being excreted or fixed in the tissues. Since arsphenamin is eliminated much more slowly than neoarsphenamin it is probable that the arsphenamin fixed by the tissues is oxidized to the parasitocidal oxid much more slowly than neoarsphenamin which is more rapidly oxidized and eliminated. I will, however, later discuss these questions in more detail in relation to the absorption and elimination of arsphenamin and neoarsphenamin and the bearing these have in addition to the question of rapidity of oxidization, upon the treatment of syphilis with special reference to the choice of compounds in the treatment of the acute *versus* chronic stages of this disease.

Theory of Antibody Production.—While the trypanocidal activity of the pentavalent and trivalent arsenical compounds appears to depend upon the production *in vivo* of new compounds by processes of oxidation and reduction, the question arises whether curative activity is aided by the production of antibodies. Not infrequently one hears that the curative activity of mercury and the arsenical compounds in syphilis is due to the fact that these substances stimulate the body cells to produce antibodies for *Sp. pallida* and that the same processes may be operative in the cure of trypanosomiasis.

As stated in Chapter XI there is evidence to show that a temporary period of immunity follows the cure of trypanosomiasis of mice treated with various dyes. This is also true after cures effected by atoxyl, arsacetin and arsenophenylglycin although this immunity is of very brief duration following cures of *Tr. equiperdum* infections of rats with arsphenamin and neoarsphenamin.

The question naturally arises, is the cure of trypanosomiasis by a single large dose of an arsenical, antimonyl or other trypanocidal compound aided by the production of antibodies or is it a matter primarily and solely of chemical destruction by products of the drugs? The possible role of curative immunity in chronic infections is a different matter because time is afforded for the production of immune principles. What are the chances of immunological cures in acute infections of mice and rats?

Uhlenhuth and Woithe[43] stated in 1908 that atoxyl probably owed some of its trypanocidal activity to an influence upon antibody production but were unable to produce experimental evidence in favor of the theory. Terry[44] found that the administration of arsacetin prolonged the excretion of dichlorbenzidin plus amidonaphtol disulphonic acid 1.8.3.6 and thereby aided the immunity engendered by this substance in mice infected with *Tr. evansi.* Weisbach[45] claimed that the administration of salvarsan results in an increase of agglutinins and complement; Ciuca[46] observed that the injection of tartar emetic and salvarsan was followed by an increase of serum complement in normal and trypanosome-infected animals, while the administration of atoxyl caused a decrease of complement in the area of normal animals and in a proportion of trypanosome infected animals; Toyama and I[47] observed that while massive doses of arsphenamin and mercuric chlorid tended to decrease the amount of complement in the serum of rabbits, smaller doses tended to augment the complement content after a primary decrease, in both human subjects and rabbits.

However, the evidence in favor of the theory that the arsenical compounds owe part of their curative activity in trypanosomiasis to an influence upon antibody production is very meager and inconclusive and during the past two years I have sought to gain additional information on this subject.

In the first place, experiments with rats have shown that the preliminary injection of single and repeated doses of alkalinized solutions of arsphenamin in amounts varying from 0.01 to 0.02 gm. per kilogram of weight, had no influence upon increasing the resistance of the rats to infection with *Tr. equiperdum* injected intraperitoneally at intervals of three to sixteen days after the last injection of the drug; that is, the medicament in these experiments did not show any evidences at all of increasing the natural resistance or immunity of these animals either by antibody production or other immunological agencies. Similar results of a negative character were observed with neoarsphenamin administered in doses varying from 0.02 to 0.03 gm. per kilogram.

Vaccines of *Tr. equiperdum* were prepared and employed for the immunization of rabbits by intravenous injection of ascending doses arranged according to body weight. At the same time some of these animals received intravenous injections of alkalinized solutions of arsphenamin in dose of 0.01 gm. per kilo and solutions of neoarsphenamin in dose of 0.02 gm. per kilo four hours after each injection of vaccine. At frequent intervals the serum of each animal was examined quantitatively for agglutinins, complement fixing antibodies (alexo-fixagins) and trypanolysins.

It was noted that the rabbit reacts poorly and tardily with the production of these antibodies for *Tr. equiperdum* even when a large number of heat killed trypanosomes have been given along the same general lines as employed for the production of immune bacterial agglutinins, hemolysins, etc., in these animals. Animals receiving the injections of arsphenamin and neoarsphenamin at the same time did not produce any more of these antibodies than animals receiving only the vaccine.

These results have shown that arsphenamin and neoarsphenamin at least do not have any appreciable influence upon increasing specific antibodies in rabbits immunized with *dead* trypanosomes; antibodies are produced but not more so in arsphenamin and neoarsphenamin treated animals than in the untreated controls.

It is of course difficult to measure the degree of immunity by test tube experiments and the chances of error are considerable, but I believe that antibody production in trypanosomiasis is seldom high and develops but slowly. Both the degree and rapidity of the immunity may be influenced by the administration of trypanocidal agents, the drug releasing antigenic principles from the parasites rather than stimulating the antibody producing tissues. The different compounds vary however, in this activity. Furthermore, these compounds act better with living trypanosomes in the production of this immunity than with vaccines of dead organisms, but I very much doubt if immunity can be produced quickly enough to aid in the cure of an acute trypanosome infection of the mouse and rat when sterilization is brought about by a powerful trypanocidal drug in a matter of sixteen to twenty-four hours.

In the treatment of chronic infections of guinea-pigs and rabbits or of acute infections of rats with repeated doses of a trypanocidal drug, immunity may aid in holding in check the infection and even in bringing about a cure, but in acute infections, this does not appear to be the case.

Route of Administration of Arsenicals in Relation to Toxicity and Trypanocidal Activity.—As will be discussed with more detail in Chapters XVIII and XIX, the route of administration of the arsenicals is a subject of considerable practical importance in the chemotherapy of trypanosomiasis and syphilis. Ehrlich found quite early in his work with salvarsan that intramuscular injections were more effectual in the treatment of experimental trypanoso-

miasis and spirochaetosis than intravenous injections and some clinicians are convinced that this is true in the treatment of syphilis of human beings with arsphenamin and its substitutes. The toxicity of arsphenamin and neoarsphenamin for mice and rats is influenced by the route of administration and in the treatment of trypanosomiasis of the rat it has been observed that intramuscular injections of arsphenamin and neoarsphenamin are just as effective as intravenous injection; indeed, intramuscular injections of arsphenamin are apt to be slightly more effective than intravenous injections, as shown by Voegtlin and Smith[48], and I have found the same to be true of sulpharsphenamin. There is therefore, a great and urgent need for efficient arsenicals capable of being injected subcutaneously or intramuscularly with little or no local reaction and especially for the treatment of syphilis and trypanosomiasis of human beings, not only because this route of administration is technically easier than intravenous injections, but because the therapeutic results are likely to be better and especially for the treatment of chronic infections when slower elimination is required. Sulpharsphenamin and the new combination compounds of arsenic and bismuth are compounds of this highly desirable class.

Arsenic Resistance of Trypanosomes.—Arsenic resistance or fastness of trypanosomes is an acquired state whereby the parasites are enabled to withstand several times the dose of arsenical which originally would have destroyed them. As stated in Chapter I the phenomenon was discovered more or less accidentally by Ehrlich working with mice infected with trypanosomes and treated with arsacetin and arsenophenylglycin. Since then a great deal of work has been done on the subject of drug fastness in general and particularly with the arsenicals, tetrazo dyes (trypan-red and trypan-blue) and triphenylmethan dyes (parafuchsin) with trypanosomes, spirochetes and bacteria with the general result that acquired resistance or tolerance of parasites for drugs and poisons is known to be a general biological phenomenon observed with a multitude of chemicals and various organisms.

Browning[49] succeeded in rendering *Tr. brucei* resistant to atoxyl and arsacetin by feeding these compounds or injecting them subcutaneously in sub-curative doses. Naturally great interest attaches to the question whether or not *Tr. gambiensi* and other trypanosomes can acquire resistance to arsphenamin and neoarsphenamin as bearing a very practical relation to the treatment of African sleeping sickness as well as in relation to the treatment of syphilis. Experiments have shown that *Tr. gambiensi* and *Tr. equiperdum* do acquire resistance to both of these compounds. Voegtlin and Smith have stated that *Tr. equiperdum* injected into rats which two weeks previously had received 0.1 to 0.2 gm. of arsphenamin and neoarsphenamin respectively per kilogram of weight, acquired a resistance. I have had a similar experience on three different occasions during the past eight years. The comparative ease with which trypanosomes can be made resistant to arsphenamin, neoarsphenamin and the arsenical compounds in general, renders imperative the greatest care in laboratories carrying strains of different trypanosomes; otherwise a resistant strain may gain circulation and lead to very erroneous results and deductions in chemotherapeutic investigations. Possibly something like this happened to the strain of *Tr. equinum* reported by Halberstadter[50] as *naturally* resistant to atoxyl, arsacetin, arsenophenylglycin and salvarsan *in vitro* and *in vivo*. His strain had never been subjected to the influence of these compounds as far as he knew, but I know from experience that it is easy to be mistaken. This strain was fully susceptible to tartar emetic although Morgenroth and Halberstadter[51] found a strain rendered resistant to arsacetin likewise resistant to antimony. This arsacetin-fast

strain was likewise resistant to salvarsan and to a lesser degree to arsenophenylglycin. After discontinuing treatments, resistance to tartar emetic was lost while resistance to the arsenical compounds persisted.

Of great interest in this connection is whether trypanosomes rendered resistant to arsphenamin are likewise resistant to neoarsphenamin and the reverse. Browning found that an atoxyl resistant strain of *Tr. brucei* was resistance to arsacetin and one other derivative of atoxyl. In the treatment of trypanosomiasis therefore, probably no advantage is to be gained by "switching" from one of these compounds to the other to overcome possible resistance of *Tr. gambiensi* or other pathogenic trypanosomes. However, with less closely related arsenical compounds this group resistance is not so much in evidence. For example, the arsphenamin and neoarsphenamin resistant strains of *Tr. equiperdum* in my laboratory were susceptible to atoxyl and tryparsamid. In practice, therefore, when it is suspected that the trypanosomes have acquired as resistance to any particular medicament it is well to "switch over" to some other trypanocidal agent as far removed in chemical relationship as possible.

Curiously, as shown by Lake and Probey,[52] arsenic resistant strains may be proportionately less resistant to neoarsphenamin than to arsphenamin; for example, they found that a neoarsphenamin which was only about one-third as effective as arsphenamin with a "normal" strain was fully as effective as arsphenamin with several "arsenic-fast" strains. Voegtlin and his associates confirmed this observation but the differences were not as great. The latter also found that arsenic resistance and virulence are not related in any way and that while Mesnil and Beaumont[53] were unable to change the resistance of a strain resistant to atoxyl in mice by passing it through 43 rats, yet the resistance of their strain to arsphenamin in rats was greatly reduced by passage through rabbits and a dog, the decrease gradually disappearing however, as a result of repeated transfers in normal rats. Voegtlin and his associates also showed that if a rat is inoculated with a mixture of normal and arsenic-fast strains, the administration of an ordinary sterilizing dose of arsenoxid like 0.5 c.c. M/100 solution per kilogram of body weight, will enable one to recover the arsenic-fast strain since it resists destruction. I have accomplished the same result by administering arsphenamin in dose of 0.003 gm. per kilogram twenty-four hours after inoculation with a mixture of normal and arsenic resistant strains, the latter requiring a dose of approximately 0.015 gm. for sterilization while the normal strain was regularly killed off *completely* by 0.003 to 0.004 gm. per kilogram.

CHAPTER XIII

TOXICITY AND TRYPANOCIDAL ACTIVITY OF COMPOUNDS OF ANTIMONY

Next to organic compounds of arsenic, compounds of antimony have proven most trypanocidal, not only in the chemotherapy of experimental trypanosomiasis but likewise in the treatment of trypanosome diseases of human beings and the lower animals. Tartar emetic and other antimonyls have been also employed in the treatmemnt of various other protozoal and metazoal diseases so that the group is of much interest and importance in the chemotherapy of disease.

Trypanocidal Activity of the Antimony Tartrates.—In 1908, Plimmer and Thompson[1] first discovered the trypanocidal activity of potassium antimony tartrate and sodium antimony tartrate in rats infected with *Tr. brucei* and *Tr. evansi.* A dose of 1 c.c. of a 1-per cent. solution of the potassium salt was usually toxic in twenty-four to forty-eight hours but likewise brought about a rapid disappearance of the trypanosomes. The sodium

salt in dose of 0.35 to 0.5 c.c. of 1 per cent. solution was less toxic and caused the disappearance of trypanosomes from the peripheral blood within half an hour even when it was "swarming with the parasites." Relapses, however, sometimes occured. Plimmer and his associates continued their studies on the effect of various antimonials in rats and dogs and in conjunction with Bateman, made important experiments to determine where the trypanosomes rest during the period in which the peripheral blood is free from them after treatment with antimony, with the result that in rats trypanosomes were found to live longest in the bone marrow and liver.

At the same time and independently Mesnil and Brimont[2] made extensive studies with the double tartrate of antimony and potassium (tartar emetic) and found that its trypanocidal activity varied considerably with different strains of trypanosomes. Thus *Tr. evansi* (surra) infections of mice were generally cured by one injection of 0.3 to 0.35 mgm. per 20 grams of weight; when relapses occurred cures were effected by additional treatments. One strain of surra (*mauritius*) employed for infecting 25 mice was atoxyl-fast but was readily influenced by tartar emetic since 21 of the mice were cured. Similar results were observed in the treatment of mice infected with *Tr. equiperdum* (dourine). With mice infected with *Tr. brucei* (nagana) and *Tr. equinum* (caderas), however, the results were not so good; following an injection, the trypanosomes usually disappeared for a while but relapses occurred continually and most of the mice succumbed. In *Tr. gambiensi* infections of rats the injection of 1 mgm. per 10 grams of weight usually brought about a temporary disappearance of trypanosomes, but relapses generally occurred in four to sixteen days; the animals gradually lost weight and finally succumbed if not to trypanosomiasis, then to the effects of repeated injections of the medicament. Boyce and Breinl[3] were less successful with sodium antimony tartrate in the treatment of rats infected with *Tr. equiperdum* and stated that the local effects were very severe, causing necrosis and sloughing. Tsuzuchi[4] found tartar emetic highly trypanocidal and particularly when employed with arsenical compounds in a combination therapy.

Trypanocidal Activity of Various New Compounds of Antimony.—Breinl and Nierenstein continuing this work, prepared *p*, *m*, and *o* amino-phenyl-stibinic acids analogous to atoxyl. These new compounds were administered in the form of sodium salts to rats, dogs and monkeys infected with *Tr. brucei*, *Tr. evansi* and *Tr. gambiensi* and the *p*-compound was found to possess a fairly powerful trypanocidal action, although not as rapid in action as sodium antimonyl tartrate.

Thompson and Cushing[5] examined a number of antimony compounds in rats infected with *Tr. brucei*. Among those that were inefficient or valueless for one reason or another were diphenylstibinichlorid, potassium meta-antimoniate, colloidal antimony oxid and a glycerid of antimony. Among the best compounds were the combinations of antimony with oxyacids of the fatty series, as the lactate, citrate, malate and mucate salts. The potassium and sodium salts of the malates and tartrates were equally trypanocidal, but it was thought that the substitution of an alkyl radicle for the potassium or sodium of the salts seemed to have some advantage. Best results were observed with solutions of ethylantimonyl tartrate, prepared by heating freshly precipitated antimony oxid with ethyl tartrate to about 150°C. in sealed tubes. A combination therapy of atoxyl and ethylantimony tartrate did not yield appreciably better results than the latter alone, the mixtures being more toxic and scarcely more trypanocidal.

The next notable contribution to this subject was made by Rountree and Abel.[6] Three new compounds were prepared, the triamid of antimony thioglycollic acid, a new antimony-thioglycollic ester and sodium antimony thioglycollate. The ester, however, had such a low solubility in water that it was not regarded as suitable for therapeutic tests. Trypanocidal tests with the remaining two compounds were conducted with rats, dogs, rabbits and a donkey employing *Tr. brucei*, *Tr. evansi* and *Tr. equiperdum*. Both appeared to possess equal or possible slightly greater trypanocidal activity than tartar emetic and possessed the advantage of being better adapted for subcutaneous injection. Most interest was shown in the antimonylthioglycollate, in solutions of which the antimony occurs as a complex organic ion.

Uhlenhuth, Mülzer and Hügel[7] found a colloidal preparation of antimony effective in repeated doses, but most of their work was carried out with hen spirillosis and rabbit syphilis, to which I will make further reference in Chapter XXVII. Kolle, Hartock and Rothermundt[8] observed particularly good results in the treatment of mice infected with *Tr. brucei* with organic and inorganic compounds containing antimony in trivalent form. Antimony trioxid ("trixidin") in 30 per cent. suspension in oil was particularly non toxic upon intramuscular injection and was stated to yield a chemotherapeutic index of 1:100. Metallic antimony in oil suspension was likewise effective as also tartar emetic, dimethylphenylpyrazalon, dimethylphenylpyrazalonacethyl antimony trichlorid, etc. Kolle and his associates also showed at this time that it is possible to influence and even cure as many as 66 per cent. of mice, rats, guinea-pigs, rabbits and monkeys infected with *Tr. equiperdum*, *Tr. brucei* and *Tr. gambiensi* by inunctions of ointment containing metallic antimony. The establishment of "depots" of the medicament by cutaneous application or intramuscular injection results in the drug being more slowly absorbed and eliminated yielding thereby a more prolonged effect. In a subsequent article Kolle, Hartock and Shürman reported additional experiments with antimony trioxid ("trixidin"). Intramuscular injections in rabbits, dogs and monkeys produced abscesses, but therapeutic success followed the intravenous injection of particularly fine suspensions in saline solution prepared from tartar emetic, in the treatment of donkeys infected with *Tr. brucei*, dogs and guinea-pigs infected with *Tr. equiperdum* and rabbits infected with *Tr. brucei* and *Tr. equiperdum*. Multiple doses were usually required. Hoffman[9] confirmed this work with antimony trioxid, establishing the toxic dose for rabbits by intravenous injection of suspensions in 20 per cent. glucose, 10 per cent. gum arabic or best of all, in a 7.5 per cent. gum arabic and 20 per cent. glucose solution, as about 0.100 to 0.120 gm. per kilogram of weight and the curative dose 0.045 gm. per kilo for *Tr. brucei* infections and 0.025 to 0.030 gm. per kilo for *Tr. equiperdum* infections. Horst[10] has likewise reported upon the curative activity of antimony trioxid, calling attention however, to the accidents caused by embolism when suspensions are injected intravenously. Tartar emetic was likewise found trypanocidal.

Voegtlin and Smith,[11] have recently renewed interest in the trypanocidal activity of salts of antimony with special reference to antimonyllactate. Especially good effects were noted with antimonythioglycollate, first used by Rountree and Abel as discussed above, tartar emetic and antimonyllactate. White rats and *Tr. equiperdum* were employed, the trypanocidal tests being conducted by their method and yielding chemotherapeutic indices varying from 3 to 6. In trypanocidal tests after my own method, tartar emetic yielded an index of 3.

Fargher and Gray[12] have recently prepared a series of compounds of antimony and tested their toxicity upon mice by intravenous injections; trypanocidal tests were not conducted and it is not possible therefore, to express an opinion of their comparative chemotherapeutic values. These compounds comprised the salts of the alkali metals, cinchona alkaloids, anilin and other substances. The percentage of antimony varied from 46.56 in a partially polymerized mixture of sodium phenylstibinate to 17.11 in cinchonine antimonyl tartrate. Toxicity varied from 0.174 gm. per kilogram of weight of sodium m-acetylaminophenylstibinate to 0.010 gm. per kilogram of barium antimonyl tartrate.

Mechanism of Trypanocidal Activity of Antimony Compounds.—The majority of investigators in this field have noted the rapid disappearance of trypanosomes from the blood of infected animals after the administration of some antimony compounds, and especially after intravenous infections. Some antimony compounds appear to exert an immediate toxic effect upon the parasites, the resistance of different species varying, however, in susceptibility to this toxic action. The effects are so rapid in the case of trivalent compounds that there is practically no basis at all for the theory that antimony is not primarily trypanocidal, but speeds up the production of antibodies which are the active trypanocidal agents. Voegtlin and Smith have seen no evidences of agglutination or phagocytosis of trypanosomes in the blood stream preliminary to their disappearance. Apparently they are first rendered incapable of multiplication, followed by death and extremely rapid disappearance from the blood probably largely by cytolysis through the agency of autolytic or blood enzymes.

As shown by Voegtlin and Smith, a pentavalent antimony compound (antimonic potassium tartrate prepared by oxidizing a solution of antimonyl-potassium tartrate with chlorin gas) was of low toxicity for both rat and trypanosomes whereas a trivalent compound (antimonyllactate prepared from lactic acid and antimony trioxid) while more toxic for the host, was likewise more toxic for the trypanosomes. As mentioned above Kolle and his associates have long maintained that the trivalent compounds were more trypanocidal than pentavalent compounds. Voegtlin and Smith have also observed that the toxic effects and trypanocidal activity of the trivalent compound occurred more rapidly than in the case of the pentavalent compound and on the basis of their results advanced the theory that the pentavalent compounds first require reduction to the trivalent form before marked trypanocidal effects may occur; an exactly similar theory has been advanced by these investigators to explain the trypanocidal activity of arsenical compounds as discussed in Chapter XII.

Nothing is known of the influence of immunological factors in relation to the trypanocidal activity of antimonyl compounds. In my experiments after the cure of *Tr. equiperdum* infections of rats with tartar emetic (0.020 gm. per kilogram), a period of immunity of five days follows during which the animals cannot be re-infected. The resistance following this dose of emetic alone in control rats does not usually last longer than 36 hours.

This immunity following cure is analogous to that first observed by Ehrlich and Shiga following the cure of *Tr. brucei* infections of mice with trypan-red discussed in Chapter XI. A similar immunity follows the cure of trypanosomiasis of rats with organic arsenical compounds, as discussed in Chapter XII. I believe that this immunity apparently engendered by antigenic principles released from living trypanosomes by antimonyl compounds, may and probably does, exert a curative activity in the treatment of chronic trypanosomiasis of human beings and the lower animals, but plays

no part at all in the cure of acute infections with single large doses of antimonyl compound.

Acquired Resistance of Trypanosomes to Antimony.—As previously mentioned in preceding chapters it is comparatively easy to render trypanosomes "resistant" or "fast" to the dyes and arsenical compounds. Much less work has been conducted along these lines with the antimonyl compounds.

Halberstadter[13] has reported that a strain of *Tr. equinum* naturally (?) resistant to atoxyl, arsacetin and salvarsan could not be rendered resistant to tartar emetic. Morgenroth and Halberstadter[14] however, were able to render an acquired arsacetin fast strain resistant to tartar emetic by a single treatment. Mesnil and Brimont[15] observed that a strain of *Tr. evansi* which was atoxyl resistant, also developed resistance or tolerance for tartar emetic. With *Tr. brucei*, however, the results were more doubtful. Rountree and Abel were unable to render *Tr. brucei* definitely resistant to sodium antimony thioglycollate, their work in this subject being summed up in the statement that "resistance has not been noted in the prolonged treatment of any single species of animals infected with nagana and that the only phenomena suggesting tolerance have been encountered in the strain which was subjected to treatment in two different hosts, the donkey and the rat." Working with tartar emetic administered in subcurative doses to rats infected with *Tr. equiperdum*, I have succeeded in rendering the parasites appreciably more resistant to this compound after fourteen transfers; the strain, however, had shown no variations in virulence for mice and rats and no change in susceptibility to arsphenamin and neoarsphenamin. I believe, therefore, that trypanosomes can be made antimony-resistant, but not as quickly or readily as they may be rendered arsenic-resistant.

CHAPTER XIV

TRYPANOCIDAL ACTIVITY OF MERCURIAL COMPOUNDS

Although inorganic and organic compounds of mercury are known to possess spirocheticidal properties and have been employed for hundreds of years in the treatment of syphilis, their trypanocidal activity is very feeble. Even when administered in amounts approximating the maximum tolerated

doses for animals infected with different kinds of trypanosomes, there are no demonstrable trypanocidal effects at all or, at most, a mere retardation of development of trypanosomiasis for a day or two as compared with untreated controls.

Mercurial compounds, however, are not entirely devoid of trypanocidal effects; this can be shown by *in vitro* or better still, by combined *in vitro* and *in vivo* tests to which I will shortly refer. The lack of trypanocidal effects *in vivo* appears to be due in large part to the high toxicity of these compounds preventing the administration of sufficiently large doses. They do not, however, possess anywhere near the trypanocidal activity of the arsenobenzols; arsphenamin, for example, is frequently trypanocidal in my test in dose of 0.002 gm. per kilogram of rat whereas mercuric chlorid and other soluble salts of mercury in dose of 0.002 gm. per kilogram by intravenous injection are without appreciable effects. The mercurial compounds as a class are far more spirocheticidal than trypanocidal, which subject is discussed in Chapter XXIV.

Owing to the importance of mercurial compounds in the treatment of syphilis, it is not surprising that numerous investigators have attempted to prepare new organic compounds of decreased toxicity for the host with increased toxicity for parasites. It may be stated, however, that no one has as yet succeeded in preparing compounds possessing a notable decrease in toxicity for the body cells along with markedly enhanced trypanocidal and spirocheticidal properties.

Mercurial Compounds in the Treatment of Acute Trypanosomiasis.—The results of trypanocidal tests conducted by Schamberg, Raiziss and myself[1] with *Tr. equiperdum* and various known and new compounds of mercury, all of the latter being prepared in our laboratory, the doses administered being usually as much as the maximum tolerated amounts for white rats by intravenous and intramuscular injection, have yielded generally negative results when compared with the untreated controls included in each experiment. *Tr. equiperdum* was employed routinely, but some compounds were re-tested against *Tr. brucei* and *Tr. lewisi* with similar negative results. Occasionally the development of trypanosomiasis was delayed for one or two days in the treated animals and their lives correspondingly prolonged, but in no instance have we been able to cure infected animals. On numerous occasions I have sought to make the tests more sensitive, that is, more favorable for eliciting trypanocidal properties, by infecting rats with minimal numbers of organisms and administering the mercury compounds at once or within a few hours, but with generally negative results insofar as complete sterilization was concerned. Negative results were likewise observed in the treatment of rats with divided daily doses of mercury compounds; always, however, the infection rapidly gained and proved fatal in almost the same period of time as in untreated controls.

Mercurial Compounds in the Treatment of Chronic Trypanosomiasis. Naturally one would expect better results in the treatment of chronic trypanosomiasis of the rabbit permitting the administration of various mercurials over a long period of time; but in my experience the curative effects have been but slight or doubtful. With the assistance of Miss Anna Rule, I have infected a large series of rabbits with intravenous injections of approximately 500,000,000 *Tr. equiperdum*, beginning treatment about three weeks later. The results summarized in the following table are chosen from the series to illustrate the general findings, and it will be observed that the mercurials administered were without marked or constant curative effect upon the trypanosome infections. Indeed, some of the treated animals succumbed earlier

than the untreated controls, due to a summation of the toxic effects of the mercury and infection:

MERCURIAL COMPOUND IN THE TREATMENT OF CHRONIC TRYPANOSOMIASIS

RABBIT	COMPOUND	ROUTE OF ADMIN.	DOSE PER 60 KILO (GM.)	NUMBER OF DOSES	INTERVAL OF ADMIN.	RESULTS
1	Bichlorid	Intravenous	0.015	6	Daily	Lived 50 days
2	Bichlorid	Intravenous	0.015	3	Daily	Lived 33 days
3	Bichlorid	Intravenous	0.015	4	Twice weekly	Lived 42 days
4	Bichlorid	Intravenous	0.015	6	Twice weekly	Lived 56 days
5	Mercurial ointment	Inunction	0.6	16	Daily	Lived 61 days
6	Mercurial ointment	Inunction	0.6	8	Daily	Lived 51 days
7	Mercurial ointment	Inunction	0.6	7	Daily	Lived 31 days
8	Mercuric salicylate	Intramuscular	0.06	5	Weekly	Lived 63 days
9	Mercuric salicylate	Intramuscular	0.06	4	Weekly	Lived 25 days
10	Control	.....	.....	..	.....	Lived 23 days
11	Control	.....	.....	..	.....	Lived 37 days

All of our animals finally succumbed with the lesions of trypanosomiasis in some of which and notably those of the testicles and prepuce, manp motile trypanosomes were observed by microscopical examination. But it would appear that the mecurials are not entirely without effect as shown by the prolongation of the lives of some receiving the most treatment.

Trypanocidal Activity of Mercurial Compounds in Combined in Vitro-in Vivo Tests.—That mercurial compounds possess trypanocidal activity *in vitro* is readily shown in tests conducted with my combined *in vitro-in vivo* method described in Chapter X. In this method equal parts of the blood of rats heavily infected with *Tr. equiperdum* and varying dilutions of the medicament were mixed and kept in a water bath at 38°C. for 15 minutes when a portion of each mixture was injected into rats to determine the degree of trypanocidal activity. In tests of this kind bichlorid of mercury was sometimes found trypanocidal in final dilutions as high as 1:2500; suspensions of calomel were not trypanocidal in this dilution. A few of the new compounds prepared by Raiziss were trypanocidal in dilutions as high as 1:4000. The superior activity of arsphenamin, however, was shown by the fact that dilutions as high as 1:16,000 to 1:20,000 were trypanocidal in the same tests.

Toxicity and Trypanocidal Activity of Organic Combinations of Mercury and Arsenic.—From the standpoint of the chemotherapy of syphilis it would appear that organic compounds containing both mercury and arsenic would prove of especial interest in view of the possibility of employing both remedies in the one compound. With this in view, Raiziss, Gavron and myself prepared a number of such compounds, the chemistry, toxicity and trypanocidal effects of which are described elsewhere.[2] These new compounds belonged to a class of half complex aromatic organic arsenical compounds into which mercury was introduced. Owing to the presence of 32 to 40 per cent. of mercury the maximum tolerated doses were as low as 5 to 10 milligrams per kilogram of weight. The arsenic content varied from 11 to 15 per cent. in the different compounds and from this standpoint offered encouragement for expecting some trypanocidal activity but in actual tests the group of compounds proved disappointing in this regard due presumably, to the fact that the arsenic was too firmly bound or was not available in an active state.

Influence of Mercurial Compounds upon Antibody Production in Trypanosomiasis.—It is frequently stated that part of the curative activity of mercurial compounds in syphilis is due to the fact they stimulate the body

cells to produce antibodies for *Sp. pallida*. As discussed in Chapter XXIV I have not in my experiments been able to substantiate this theory. I also have considered worth while a study of the possible influence of mercury upon antibody production in trypanosomiasis and especially in relation to the whole question of the influence of drugs upon antibody production in general and more especially in syphilis.

Rabbits were immunized by weekly intravenous injections of a vaccine of *Tr. equiperdum*. Some animals received in addition, the intravenous injection of 0.0005 gm. mercuric chlorid per kilogram of weight four hours after each injection of vaccine. Others received intramuscular injections of salicylate of mercury in olive oil in dose of 0.001 gm. per kilogram (equivalent to 1 grain per 60 kilograms). Five days after each injection, the sera of all rabbits were tested quantitatively for agglutinins, alexo-fixagins and trypanolysins. After nine injections the antibody content of the rabbits receiving vaccine alone was the same as found in the rabbits receiving vaccine and mercurial compounds. In other words, the mercurials given in doses per kilogram of weight corresponding to those ordinarily employed in the treatment of syphilis of human beings, had no influence upon increasing antibodies engendered by immunization with a vaccine of dead trypanosomes.

However, since it appears that antibody production in trypanosomiasis is produced in highest degree by *living* rather than dead trypanosomes, these experiments were not considered conclusive. Rabbits were infected with *Tr. equiperdum;* some were treated with weekly intravenous injections of 0.00005 gm. mercuric chlorid and weekly intramuscular injections of the salicylate in dose of 0.0001 gm. per kilogram of weight. These doses were too small to exert curative influence but were considered sufficient to stimulate antibody production if this were possible. Frequent examination of the serum of each rabbit for agglutinins, alexo-fixagins and trypanolysins during the following eight weeks of the experiment, showed that the untreated controls developed these antibodies to the same degree as the treated animals. I could find no evidence of increased antibody production to be ascribed to the influence of the two compounds employed in this study.

Acquired Resistance of Trypanosomes to Mercury.—Nothing is known regarding the acquisition of resistance to mercurial compounds by trypanosomes. Since the mercurial compounds are much less trypanocidal than arsenical and antimonyl compounds, it would be interesting to determine if trypanosomes naturally resistant to a compound, could have this natural resistance increased *in vitro* and *in vivo*. As stated in Chapter XXIV Akstsu and Noguchi have succeeded in raising the resistance of *Sp. pallida* and other spirochetes to mercuric chlorid *in vitro*, but similar experiments do not appear to have been made with trypanosomes.

CHAPTER XV

TOXICITY AND TRYPANOCIDAL ACTIVITIES OF COMPOUNDS OF BISMUTH, VANADIUM AND OTHER SUBSTANCES

Since trypanocidal tests have proved so useful in the development of the chemotherapy of syphilis with organic arsenical compounds, it is not surprising that similar tests have been employed in the study of the parasitropic activity of new compounds of other metals for the treatment of this disease. Among attempts of this kind should be mentioned trypanocidal tests with compounds or bismuth, vanadium, thorium and mesothorium.

Toxicity and Trypanocidal Activity of Compounds of Bismuth.—Special interest is to be placed in some of the newer organic compounds of bismuth

and particularly the tartrobismuthates, since these have been found to possess a distinct spirocheticidal properties in various experimental infections and are proving efficacious in the treatment of some cases of syphilis. Here it may be stated, however, that the compounds of bismuth so far produced have proved almost totally devoid of trypanocidal activity. Therefore, these compounds have not proved of any value in the treatment of trypanosomiasis, but they constitute another example of how compounds without trypanocidal activity may be distinctly spirocheticidal. Indeed, as I have repeatedly stated, trypanocidal tests have proved of value only with the organic arsenical compounds for the development of the chemotherapy of syphilis.

Within the last few years, bismuth has commanded considerable attention in the treatment of syphilis and especially sodium and potassium tartrobismuthate. Balzer[1] in 1889, conducted studies on the toxicity of bismuth compounds for dogs and even suggested that they may be useful in the treatment of human syphilis, but it was not until 1916 that Sauton and Robert[2] revived interest in the subject and showed that bismuth compounds possessed curative activity in hen spirillosis.

In 1920 Sazerac and Levaditi[3] observed the curative activity of sodium and potassium tartrobismuthate in rabbit syphilis and also in the natural spirochetic balanitis of this animal (venereal infection due to *Spirocheta cuniculi*), to which I will refer in more detail in Chapter XXV. These investigators also reported that the subcutaneous injection of 0.060 to 0.100 gm. of this double salt per kilogram of weight had a temporary influence upon the course of *Tr. brucei* infections in guinea-pigs.

The trypanosomes generally disappeared from the peripheral blood in 24 to 48 hours after injection, but relapses occurred after 12 to 15 days. Even after the subcutaneous injection of amounts as large as 0.200 gm. per kilo, relapses occurred although these could be prevented for a time by repeating the dose. In one experiment the life of an infected guinea-pig was prolonged in this manner for 80 days, the untreated controls succumbing in about 25 days. Permanent cures, however, were not observed.

Adler[4] observed that the minimal lethal dose of sodium tartrobismuthate was approximately 0.0047 gm. per kilo for mice by subcutaneous injection and 0.062 gm. per kilo for guinea-pigs. When administered to mice infected with *Tr. rhodiensi* in amounts as high as the minimal lethal dose, the trypanosomes disappeared in twenty-four hours with death of the animals in forty-eight hours. Smaller doses had no appreciable effects. In guinea-pigs infected with *Tr. brucei* similar temporary effects were produced with large doses; 0.018 to 0.032 gm. per kilo were followed by relapses in 6 to 12 days with no permanent cures.

In my experiments with the soluble double salt of sodium and potassium tartrobismuthate, the immediate lethal dose for white rats by intravenous injection was found to be approximately 0.180 gm. per kilo. The injection of 0.100 gm. per kilo was usually followed by death in twenty-four hours; 0.050 gm. per kilo was fatal in about forty-eight hours and 0.020 gm. per kilo in seventy-two hours while 0.015 gm. per kilo was about the maximum tolerated dose. The intravenous injection of 0.015 gm. to 0.020 gm. per kilo had no appreciable trypanocidal effects, however, in tests conducted with rats infected with *Tr. equiperdum* according to the technic of my method; similar results were observed with sodium tartrobismuthate, potassium tartrobismuthate and bismuth trioxid.

Similar results have been observed by Myers and Corbitt[5] employing *Tr. equiperdum* in tests conducted after the method of Voegtlin and Smith. The maximum tolerated dose by intravenous injection into white rats for a

period of seven days of four different preparations of soluble preparations of sodium and potassium tartrobismuthate varied from 0.036 to 0.051 gm. per kilogram of weight; the administration of amounts varying from 0.005 to as much as 0.067 gm. per kilo had no appreciable effect upon these experimental infections, except to cause a delay of one to five days in the death of some of the animals with the infection.

In general terms, it may be stated, therefore, that bismuth compounds possess at best but feeble trypanocidal activity; they are, however, decidedly more spirocheticidal and this property will be discussed more fully in Chapter XXV.

Toxicity and Trypanocidal Activity of Compounds of Vanadium.—A thorough study of fourteen of the simple and complex salts of vanadium has been made by Proescher, Seil and Stillians.[6] The toxicity of the majority of these salts was determined by intravenous injection in rabbits and by subcutaneous injection in guinea-pigs, rats and mice. In addition the toxicity of sodium tetravanadate was determined for horses, chickens, pigeons and frogs. The toxicity of the salts studied appeared to depend on their chemical constitution and is influenced by the number of hydroxyl groups attached to a vanadium atom and the presence of the VO_2 group.

Trypanocidal tests employing *Tr. brucei* infections of mice and guinea-pigs showed that the simple vanadium salts such as sodium tetravanadate, anilin vanadate, and vanadyl sulphat may suppress the multiplication of the organisms, or temporarily inhibit the course of the disease. Complete cures could not be effected. The complex vanadium compounds, such as ammonium vanadi-arsenate, effected complete cures in about 16.6 per cent. of animals, while others as ammonium vanado-arsenate and sodium phospho-vanadate were without effect. Best results were observed by a combination of vanadium with arsenical compounds, as arsacetin.

Trypanocidal Activity of Mesothorium, Thorium and Other Substances.—Citron[10] has studied the influence of mesothorium upon pathogenic trypanosomes and found that while exposure to the rays had the effect of reducing their vitality, actual destruction could not be accomplished. I have found the maximum tolerated dose of thorium chlorid for rats to be about 0.050 gm. per kilogram by intravenous injection; doses as large as 0.040 gm. per kilogram, however, were without demonstrable trypanocidal activity in *Tr. equiperdum* infections of white rats. Frouin and Guillaumie[11] have reported that *niobium* is without effect in mice infected with *Tr. brucei;* salts of some of the rate earths as *cerium*, *yttrium* as well as *rhodium chlorid* were found slightly effective by increasing the resistance of animals to infection with trypanosomes.

CHAPTER XVI

TRYPANOCIDAL PROPERTIES OF DYES, ARSENICAL, MERCURIAL, ANTIMONYL AND BISMUTH COMPOUNDS IN VITRO

In Chapter X were described methods for determining the trypanocidal activity of substances *in vitro*. Determinations of this kind are sometimes of value, not only in relation to studies bearing upon the mechanism of trypanocidal activity of different substances, but also for furnishing data in connection with systematic studies in chemotherapy or the relationship between chemical constitution and biological activity.

Not all substances possessing high trypanocidal activity *in vitro* are trypanocidal *in vivo;* notable examples are the group of mercurial compounds which, owing to their high toxicity for the host, cannot be given animals in sufficiently large amounts to more than merely influence the course of trypanosomiasis for a day or two. On the other hand, substances possessing very little or no trypanocidal activity *in vitro* may be more active *in vivo;* in this connection it is interesting to recall that Ehrlich and Shiga made the mistake in 1904 of discarding atoxyl because their work was confined to the test-tube with negative results.

Trypanocidal tests *in vitro* may be confined to a study of the influence of the medicament upon the motility of trypanosomes or include tests for actual and complete destruction by injecting portions of the mixtures into the peritoneal cavities of mice and rats and subsequently studying the animals for blood infections over a period of not less than two weeks. Methods of this kind are required because the parasites cannot be successfully cultivated in artificial media with sufficient regularity to yield acceptable data of trypanocidal activity.

Trypanocidal tests *in vitro* have not been conducted as frequently as *in vitro* spirocheticidal tests, especially tests employing *Sp. obermeieri* and *Sp. gallinarum.* Browning[1] tested a number of the dyes *in vitro* against *Tr. brucei* and found the benzidin derivatives as trypan-red, trypan-blue and trypan-violet practically inactive, whereas the basic triphenylmethane dyes, such as parafuchsin, ethyl-violet and Dobner's violet were found actively trypanocidal. Atoxyl in 1:100 concentration was only slightly effective against motility, while arsacetin in concentration equal to 1 per cent. of the free acid was without any effect after an exposure of two hours at room temperature.

In Table 3 are summarized the results of *in vitro* tests conducted with a number of dyes and different compounds of arsenic, mercury, antimony and bismuth. These tests were conducted by mixing in small test-tubes 0.5 c.c. of citrated rat blood containing large numbers of actively motile *Tr. equiperdum* with 0.5 c.c. of varying dilutions of the compound under study. These mixtures with the controls were placed in a water bath at 37°C. for 15 minutes and the motility of the trypanosomes examined at the end of 5, 10 and 15 minutes. At the end of 15 minutes 0.5 c.c. of the controls and dilutions of compounds showing no motile trypanosomes were injected into rats intraperitoneally and the animals observed for two weeks. The + sign in the table indicates that trypanosomiasis developed as detected by daily examinations of tail blood.

Methylene blue, atoxyl, sodium arsenate, tryparsamid, and sodium cacodylate did not produce trypanolysis in final dilutions of 1:200, but all of the other compounds shown in the table dissolved the trypanosomes in solutions just a little stronger than those producing loss of motility. In the saline controls the trypanosomes were well preserved and motile at the end of fifteen minutes and proved highly infective for rats.

TABLE 3

COMPOUND	MOTILITY 15 MIN.		RAT INOCULATION TESTS	
	PRESENT	ABSENT	DILUTION	RESULTS
Trypan-red	1:20,000	1:10,000	1:10,000	+
Trypan-blue	0	1:20,000	1:10,000	+
Methylene-blue	0	1:500	1:500	−
Methyl-violet	1:60,000	1:40,000	1:40,000	−
Fuchsin (acid)	1:10,000	1:5000	1:5000	−
Safranin	0	1:80,000	1:40,000	−
Arsenious acid	1:10,000	1:20,000	1:5000	−
Sodium arsenite	1:80,000	1:40,000	1:20,000	−
Sodium arsenate	0	1:200	1:200	−
Atoxyl	0	1:200	1:200	−
Sodium cacodylate	0	1:200	1:100	+
Tryparsamid	0	1:200	1:200	−
Arsphenamin	1:320,000	1:160,000	1:160,000	−
Neoarsphenamin	1:320,000	1:160,000	1:160,000	−
Silver arsphenamin	0	1:320,000	1:320,000	−
Mercuric chlorid	0	1:5,000,000	1:2,500,000	+
Tartar emetic	0	1:10,000,000	1:5,000,000	+
Sodium and potassium tartro-bismuthate	1:200	1:100	1:100	−
Saline controls	+	0	−	+

As shown in the table tartar emetic proved most strongly trypanocidal *in vitro*, followed by mercury, arsphenamin and neoarsphenamin. The pentavalent organic and inorganic compounds of arsenic were very much less active; bismuth and the dyes were likewise relatively much less strongly trypanocidal.

In the majority of instances dilutions sufficient for destroying motility were likewise trypanocidal as determined by the rat test; exceptions occurred with trypan-red trypan-blue, sodium cacodylate, mercuric chlorid and tartar emetic. Loss of motility is not always an indication of death of the organisms, but usually this is the case; apparently some compounds may destroy motility in dilutions much higher than necessary for trypanocidal activity, but of course, the chances of experimental error are considerable inasmuch as motile parasites may escape detection in the microscopical examination of mixtures.

In a broad and general manner there is some relationship between activity *in vitro* and *in vivo* although some exceptions stand out rather sharply. For example, the trypanocidal properties of the dyes, arsenious acid, atoxyl, sodium arsenate, sodium arsenite, sodium cacodylate, tryparsamid, sodium and potassium tartro-bismuthate, are rather low *in vivo* and their influence upon motility *in vitro* is likewise relatively slight. On the other hand the activity of the trivalent organic arsenical compounds, as arsphenamin, neoarsphenamin and silver arsphenamin, is very high *in vivo* and likewise *in vitro*. Mercury, however, has relatively low trypanocidal activity *in vivo*, due in part to high toxicity preventing the administration of large doses, but

in vitro mercuric chlorid possesses in high degree the power of destroying motility, although this is not always a sign of trypanocidal activity. In other words, *compounds possessing low trypanotoxic properties in vitro are likely to have low trypanocidal activity in vivo;* however, compounds may be highly trypanotoxic *in vitro* and yet relatively inert *in vivo* when administered in the maximum tolerated amounts.

Chronic Infections with Trypanosomes Which Have Been Treated in Vitro.— Of considerable interest and significance from the standpoint of the possible development of an efficient method for active immunization in trypanosomiasis, are observations showing that the infections produced by trypanosomes previously exposed to various drugs *in vitro*, tend to become prolonged and chronic. These results are due either to a reduction of the virulence of the organisms *in vitro*, which is transmitted to new generations *in vivo*, or to the fact that the animal host is unable to engender sufficient immunity to hold the infection in check and neutralize the trypanotoxins for relatively long periods of time.

Thus Browning has observed that *Tr. brucei* in defibrinated mouse blood, exposed for tweny minutes to dilutions of parafuchsin in sugar-salt solution varying from 1:9000 to 1:300,000 and then injected into mice, required more days to appear in the peripheral blood than the controls of trypanosomes in the sugar-saline solution alone; in one instance a dilution of parafuchsin 1:300,000 inhibited the development of trypanosomiasis for three days, showing how delicate this biological test is as a means of detecting damage of the parasites. Trypanosomes exposed to parafuchsin of 1:9000 to 1:80,000 required in some instance as long as 15 days to produce infections in mice and in one instance, the infection persisted for 114 days, as compared with the usual period of life of about 4 to 5 days when mice were infected with the controls. In my *in vitro* experiments it was found that *Tr. equiperdum,* exposed to solutions of trypan-red, trypan-blue, sodium cacodylate, mercuric chlorid and tartar emetic sufficient to destroy motility were sometimes infective, but the invasiveness and virulence of these trypanosomes were appreciably reduced.

This condition of semi-immunity or reduction in virulence is analogous to what Koch produced by inoculating cattle with attenuated trypanosomes. In my opinion it is primarily due to sufficient injury *in vitro* to impair the rapidity of proliferation of the parasites *in vivo;* apparently the first parasiticidal effect to occur is this impairment of the powers of proliferation or propogation *in vivo.* Under these circumstances the animal host is better able to engender a sufficient degree of active immunity to hold the infection in check and neutralize trypanotoxins; as I will discuss in a later chapter, there is evidence to show that immunity in trypanosomiasis is engendered only by living organisms as is true of the immunity in syphilis engendered only by living spirochetes.

Under the conditions of reduced proliferative powers and consequent reduction of evasiveness on the part of the parasites, the host is enabled to engender some immunity principles and, as previously stated, this may have a bearing upon the development of a successful plan for vaccination against trypanosome diseases.

CHAPTER XVII

IMMUNITY IN TRYPANOSOMIASIS OF MAN AND THE LOWER ANIMALS IN RELATION TO CHEMOTHERAPY

Comparatively little has been done in the study of natural and acquired immunity in trypanosomiasis of human beings and the lower animals, as compared with immunological studies in syphilis and bacterial infections. Probably in large part this is due to the fact that the importance of the subject has not been sufficiently great, because trypanosomiasis of human beings is fortunately confined to portions of Africa and to Chagas disease of Brazil instead of being world wide in distribution.

Natural Immunity in Trypanosomiasis.—Apparently human beings possess a high degree of natural immunity to practically all of the trypanosome diseases of the lower animals, excepting those produced by *Tr. gambiensi* and *Tr. rhodesiense.* Whether this is due in part to the fact that the flies, fleas and bugs, acting as intermediate hosts for these pathogenic trypanosomes of the lower animals, do not feed on or bite human beings, cannot be definitely stated; it is more probable that the blood and fixed tissues of human beings possess natural resistance or immunity. The nature of this natural immunity, however, is not understood, just as the mechanism of natural immunity of man to many of the bacterial diseases of the lower animals and of the lower animals to syphilis and many of the bacterial diseases of human beings, is not understood. The few investigations that have been made indicate that the trypanosomes are unable to survive and proliferate in the blood of the immune species, either as the result of the presence and activity of trypanolysins or the lack of suitable vitamins and pabulum (athreptic immunity).

Presumably all human beings are susceptible to infection with virulent strains of *Tr. gambiensi* and *Tr. rhodesiense;* in certain districts of Africa, however, notably in Nigeria, where sleeping sickness has been long endemic, the disease is less virulent and much more amenable to treatment than in Uganda, on the Congo and in Angola. This suggests that in time the population may either develop some degree of immunity or, rather, that the virulence of the trypanosomes is reduced, analogous to the gradual reduction in the virulence of syphilis during the past four hundred years in those peoples among whom the disease has been endemic. In some parts of Africa whole native villages have been depopulated by trypanosomiasis. Europeans are likewise susceptible and especially so are the younger individuals of both races. Instances of presumably individual immunity are not lacking, but these are probably due to protection against the bites of infected flies rather than an inherent and efficient degree of natural immunity. Even the offspring of recovered cases of African trypanosomiasis are susceptible to infection.

Acquired Immunity in Trypanosomiasis.—The question naturally arises whether infected human beings ever recover spontaneously from trypanosomiasis. Manson and others state that, although spontaneous recovery may take place in the early stages of trypanosomiasis, when the disease has arrived at the late stage death is inevitable. The same is true of most of the trypanosome diseases, natural and experimental, of the lower animals. In

other words human beings and the lower animals are not able to engender sufficient immunity principles in the blood, lymph and fixed tissues to effectually bring about spontaneous recovery, in the majority of instances, in virulent trypanosome infections. This is in conformity with our experience and information in immunity in protozoan infections in general. For example, in malaria and syphilis, sufficient immunological factors may be engendered and mobilized to throw the infectious agents into periods of latency and reduced virulence for varying periods of time, but without bringing about complete recovery except, possibly, in doubtful and exceptional instances.

Antibody Production in Trypanosomiasis.—In trypanosomiasis of human beings and the lower animals antibodies may be produced in the blood but seldom to a high degree. Agglutinins may be found and especially in the terminal stages; likewise complement-fixing antibodies (alexo-fixagins) and trypanolysins. The alexo-fixagins are especially apt to be found in the blood-serum and notably in dourine of horses, but it may be that these are not true antibodies in the sense of being destructive for the parasites; rather they may be analogous to the "reagin" produced in syphilis and responsible for the complement-fixation and flocculation reactions of this disease. In my opinion this "reagin" in syphilis may be regarded as a reactionary product of the lymphocytes and other cells surrounding *Sp. pallida*, without possessing more than a feeble destructive effect upon the spirochetes; and since spontaneous recovery in trypanosomiasis of human beings and the lower animals is exceptional, despite the presence of these antibodies, it is possible that the alexo-fixagins of trypanosomiasis have a similar origin and significance.

In acute trypanosomiasis of mice and rats fatal in 3 to 10 days, antibodies are not usually found at all owing to the acuteness and early fatal character of the infection. If, however, the infection is held in check by the administration of arsphenamin or neoarsphenamin in such doses as produce relapses without complete cure, the animals can be kept alive for weeks, and under these circumstances complement-fixing antibodies gradually appear being first demonstrable in my experiments about seven days after infection. In rabbits and guinea-pigs the production of complement-fixing antibodies also takes place, first appearing in *Tr. equiperdum* infections of rabbits about five days after infection.

Rôle of Immunity in the Chemotherapy of Acute and Chronic Trypanosomiasis.—It will be understood, therefore, that in acute trypanosomiasis of the mouse and rat there is practically no chance for the production of immunity principles, since the production even in chronic infections tends to be slight and tardy. There is therefore, no reason for believing that immunity principles aid in the cure of acute trypanosomiasis, when single large doses of arsenical, antimonyl, bismuth or other trypanocidal compounds are given; there is not sufficient time for the intervention of immunological processes, inasmuch as sterilization is a matter of hours instead of days and is to be attributed to the direct trypanocidal activity of reduction or oxidation products of the chemical compounds.

In chronic trypanosomiasis, however, immunity undoubtedly plays a part in holding the infection in check and may even produce varying periods of latency. This is especially true of infections treated with substerilizing doses of the dyes, arsenicals and other trypanocidal compounds. Under these conditions the medicaments appear to aid in the production of antigenic substances from living trypanosomes; I do not believe that the drugs actually stimulate the antibody-producing tissues to any appreciable degree although in large doses they may depress them, but may aid in the production of antibodies by releasing antigenic substances from the parasites.

Immunological processes may likewise play some part in the temporary period of latency in trypanosomiasis following the administration of subcurative doses of various trypanocidal agents which is discussed in a succeeding section.

Immunity Following Cure in Trypanosomiasis.—While some degree of immunity may develop in chronic trypanosomiasis of both human beings and the lower animals, which may be accompanied by the production of antibodies in the serum and spinal fluid, this immunity is usually not sufficient for bringing about complete and spontaneous cure in virulent infections. Rats infected with *Tr. lewisi*, however, generally recover spontaneously after 4 to 8 weeks and these are usually immune to re-infection with *Tr. lewisi*, although just as susceptible as normal control rats to such pathogenic parasites as *Tr. brucei* and *Tr. equiperdum.* This immunity, however, is not absolute. In my experience it tends to diminish after 18 days and the animals may sometimes be infected at this time by the intraperitoneal injection of very large numbers of the same strain of *Tr. lewisi.*

A very curious phenomenon is the temporary immunity following the cure of trypanosomiasis in mice and rats. In 1904, Ehrlich and Shiga[1] discovered that mice infected with *Tr. equinum* and cured with trypan-red, were resistant to re-infection with these trypanosomes for about 20 days. Experiments showed that the immunity was not due to unexcreted dye, as mice treated with dye alone in the same way were susceptible. Furthermore, the immunity after cure was specific only for the trypanosomes employed; the mice were just as susceptible as normal controls to other strains.

Terry[2] made a particularly thorough study of this immunity and confirmed these observations in experiments employing mice infected with four different strains of pathogenic trypanosomes and a number of dye and arsenical compounds and combinations of these.

If the curative activity of single large doses of trypanocidal agents, including the dyes and compounds of arsenic, antimony, etc., are due to the production of new reduction- or oxidation-products *in vivo* having a direct trypanotoxic activity without the aid or intervention of antibodies, what is the nature of this temporary period of resistance to re-infection after a cure has been brought about? Furthermore, what is the nature of the mechanism whereby, after the administration of a subcurative dose, trypanosomes disappear for a time and then reappear as a recurrent or relapsing infection with a fatal termination? Are these effects due to the presence and temporary activity of unexcreted medicament? Are they due to immunity principles? Or are they due to a combination of these?

Influence of Unexcreted Medicament upon Temporary Resistance.—If they were due to unexcreted medicament it should be possible to give the drugs to normal rats and then find them resistant to infection with trypanosomes for a varying period thereafter. Ehrlich found that this was not the case with dyes and Terry confirmed his results; that is, dyes injected into normal mice did not protect them against infection, whereas infected mice cured with the same doses remained refractory to re-infection for a brief time thereafter.

Are similar results to be observed in the case of the organic arsenical compounds? Terry found that atoxyl and arsacetin acted in much the same way, but the results were not as conclusive as observed with the dyes or with combinations of the dyes and arsenical compounds.

I have experimented with arsphenamin and neoarsphenamin with the following results. When arsphenamin was administered to rats by intra-

venous infection in dose of 0.004 to 0.010 gm. per kilogram 24 *hours before infection*, trypanosomiasis usually developed as in the untreated controls; whereas, when administered just before infection or 24 hours after, infection did not occur. In other words, these amounts were apparently excreted within 24 hours and similar results were observed with 0.005 to 0.015 gm. of neoarsphenamin per kilogram. However, the injection of 0.020 gm. of arsphenamin or 0.040 gm. of neoarsphenamin per kilogram 24 hours before infection generally prevented trypanosomiasis, indicating that a sufficient amount remained in the rats at the end of 24 hours to kill the trypanosomes injected intraperitoneally.

Additional experiments consisting of injecting the drugs 48 and 72 hours before infection yielded practically the same results; that is, unless the amounts administered were very large, the animals could be infected almost as readily as untreated controls. These experiments demonstrated, therefore, that the period during which ordinary doses of arsphenamin and neoarsphenamin remains curative after intravenous injection is quite brief and if a temporary resistance or immunity to re-infection follows a cure it cannot be ascribed to the activity of unexcreted medicament. Furthermore, the period of two to fifteen days following the injection of 0.001 to 0.003 gm. of these compounds per kilogram, during which trypanosomes are not to be found in the blood, can hardly be ascribed to the influence of unexcreted drug.

In this connection I may state that in additional experiments I injected rabbits every three to four days with 0.020 gm. of arsphenamin per kilogram for six doses in order to store some of the compound in the tissues. The blood and heavy emulsions of the brain, liver, kidneys, spleen and muscles of each animal were then injected in large doses into infected rats, to determine if they contained enough of the arsphenamin or its products to influence the infections. With the exception of the liver preparations the results were negative. In all instances the liver suspensions retarded the development of trypanosomes to a slightly greater degree than the controls of liver from untreated animals, but the differences were not marked and indicated at best but a slightly increased trypanocidal activity of the liver extracts of the arsphenaminized animals. In other words, the results showed that the stored arsenic is not therapeutically active, or if so, but in a slight degree.

Resistance to Re-infection Following the Cure of Trypanosomiasis by Arsphenamin and Neoarsphenamin.—I have not observed in trypanosomiasis of rats the same degree of so-called immunity following cure with arsphenamin and neoarsphenamin that Terry observed in mice cured with trypan-red, atoxyl and mixtures of these, or in mice infected with *Tr. brucei* and cured with atoxyl and arsacetin reported by Browning.[3]

Arsphenamin in dose of 0.020 gm. per kilogram and neoarsphenamin in dose of 0.040 gm. intravenously 24 hours before the intraperitoneal injection of 500,000 *Tr. equiperdum* generally prevented infection. When these compounds were injected three or more days before inoculation, infection occurred as in the untreated controls.

When rats were first infected and treated with the same doses about 40 hours later when trypanosomes were in the blood, the organisms disappeared in the following 24 hours. If these animals were now re-inoculated with trypanosomes at the end of this first day, infection did not occur; but if they were re-inoculated three or more days after treatment, infection always occurred, although in some instances the time of first appearance of the trypanosomes in the peripheral blood was delayed beyond the controls. This showed that there was practically none or but a slight degree of immu-

nity following the cure of 40-hour *Tr. equiperdum* infections of rats with arsphenamin and neoarsphenamin, since the results could be ascribed in large part to unexcreted drugs.

When rats were first infected and treated 72 hours later at a time when the blood was swarming with trypanosomes, it was found that the organisms disappeared in the following 24 hours. With arsphenamin-treated rats re-infection could not ordinarily be produced by inoculating trypanosomes within a period of four days following the treatment, but with neoarsphenamin re-infection could be accomplished in three days after treatment. This showed that the cure of heavy trypanosome infections with arsphenamin was followed by a brief period of resistance to re-infection; with neoarsphenamin this period was shorter and less definite.

Nature of the Temporary Immunity Following Cure in Trypanosomiais.—What is the nature of this temporary resistance? Ehrlich, Terry and others have called it an immunity and some investigators claim that the blood-serum during this period is trypanocidal *in vitro* and slightly curative *in vivo*.

This immunity, however, is of a very curious nature and absolutely specific for the particular strain used in producing the infection. For example, Browning infected mice with a parafuchsin-resistant strain of *Tr. brucei* and after curing the animals with atoxyl found that they could not be re-infected with the same parafuchsin-resistant strain for about ten days, but that they could be readily infected with an atoxyl-resistant strain of *Tr. brucei*. One would expect that an immunity following the cure of *Tr. brucei* infection would be effective against all strains of this trypanosome, but this is not the case; similar results were observed by Terry with different strains of *Tr. equinum*.

Apparently the trypanocidal drugs liberate from trypanosomes *in vivo* antigenic substances capable of engendering temporary periods of highly specific immunity. Arsphenamin and neoarsphenamin, however, are apparently less active in this particular than atoxyl, arsacetin and arsenophenylglycin.

As will be discussed presently, with dead trypanosomes practically no immunity results after the administration of drugs; *apparently, living trypanosomes are required for the production of the antigenic principles,* but even with living *Tr. equiperdum* infections of rats, arsphenamin and neoarsphenamin do not produce more than the briefest period of immunity after cure.

Relation of Chemotherapy to the Production of Immunity by Living Trypanosomes.—As just stated, the administration of arsphenamin and neoarsphenamin do not appear to aid appreciably in the production of antibodies by dead trypanosomes. But do drugs, and particularly the arsenical compounds, increase antibody-production by living trypanosomes? This is the question of paramount importance, because immunity in trypanosomiasis is very similar to immunity in syphilis in that the presence of the *living* parasites in the tissues appears to be required for the production of states of resistance to re-infection and immunity.

In my experiments, rabbits infected with *Tr. equiperdum* and treated weekly with intravenous injections of 0.0005 gm. arsphenamin and neoarsphenamin per kilogram (about one tenth of the minimal curative dose) have actually shown the production of more agglutinins, alexo-fixagins and trypanolysins than untreated controls, although the amounts of these antibodies were small and their production was tardy, being but slightly more than recorded above as engendered by vaccines of dead trypanosomes.

An additional experiment was conducted by infecting 8 rats with *Tr. equiperdum.* Two days later these showed approximately 750,000,000 per cubic millimeter of blood. Four of these rats were treated with the intravenous injection of 0.020 gm. of neoarsphenamin per kilogram, sufficient to effect sterilization. At daily intervals thereafter one rat was re-inoculated and on the third day after treatment it was found possible to re-infect, the immunity having lasted but three days after cure.

The four remaining rats were killed when the blood contained about 420,000,000 trypanosomes per cubic millimeter and the blood of each collected into citrate solution and the trypanosomes killed by heating in a water bath at 60°C. for one hour. Each blood-vaccine was now injected into a fresh rat and these were then treated with the same dose of neoarsphenamin to determine if an immunity would follow and if so, how it compared with that produced with the destruction of living organisms. A rat was re-inoculated, therefore, at daily intervals with living trypanosomes and infection occurred each time. At the same time 4 more normal rats were injected with the drug alone in the same dose and a rat inoculated each day to determine the influence of unexcreted drug. In this series it was possible to infect on the first and each of the three succeeding days after treatment. The results, therefore, may be summarized as follows:

(*a*) Resistance to infection following the injection of drug alone was less than one day.

(*b*) Duration of resistance to infection following treatment of living trypanosomes was about ten days.

(*c*) Duration of resistance to infection following treatment of dead trypanosomes was less than twenty-four hours.

These experiments showed, therefore, that a temporary immunity follows the cure of rats infected with living *Tr. equiperdum* by the intravenous injection of arsphenamin and neoarsphenamin. *They have also shown what has heretofore not been demonstrated, namely, that the immunity does not follow if the rats are first inoculated with dead instead of living trypanosomes before treatment is given. In other words, the development of the immunity requires that living trypanosomes shall be destroyed in the animal by some trypanocidal agent.*

Whether or not immunity follows the cure of human beings infected with *Tr. gambiensi* I am unable to state. Presumably it does for a temporary period at least, if the results of experiments in the lower animals are applicable to human trypanosomiasis. I have not been able to find records of cases of re-infection of human beings where the question of relapse could be definitely excluded. From the standpoint of animal experimentation, I believe it may be reliably state that one attack of trypanosomiasis followed by cure, does not confer an immunity against subsequent attacks with the same or other species of trypanosomes.

Duration of Infection in Relation to the Duration of the Immunity Following Cure.—Additional experiments have shown that to a slight degree the longer the trypanosomes are allowed to live in the rats before cure is effected, the longer and more definite is the resulting immunity. However, there is no definite relationship between the degree and duration of the infection and the degree and duration of the immunity following cure. Terry has observed the immunity in mice following the infection of trypanocidal agents when the infection was so light that trypanosomes could not be found in the peripheral blood.

Mechanism of Relapsing Infections.—As previously mentioned rats infected with *Tr. equiperdum* and treated with a curative dose of either arsphenamin or neoarsphenamin can be re-infected with these trypanosomes two or three days later. However, if infected rats are treated with one half of the curative doses of these compounds the trypanosomes disappear and stay out of the peripheral blood for many days, even as long as fifteen days. In other words the animals are protected against the trypanosomes of the first infection for a week or more but are susceptible to re-inoculation with fresh trypanosomes within a day or two.

This period of temporary cure is probably due in largest part to the fact that the proliferative power of the trypanosomes was injured by the drugs, so that the organisms are unable to multiply as rapidly as usual; in part it is also probably due to the immunity described above.

However, it cannot be due entirely to immunity, because, if so, the animals should be refractory to re-inoculation with small numbers of the

same trypanosomes for about as long as the period of temporary cure. Furthermore, when the trypanosomes appear again in the relapsing or recurring infection, they usually kill the mouse or rat just as rapidly as freshly inoculated trypanosomes unless treatment is given; in some instances, however, the infection persists much longer, as if the trypanosomes were held in check by immunity principles, their rate of multiplication reduced, or as if the animal had developed a tolerance for their toxic products.

As a general rule the duration of temporary cure bears a relation to the size of the dose of trypanocidal drug; this suggests that unexcreted drug may likewise exert an influence upon the duration of this period. If this is true, *the trypanosomes are apparently more susceptible to the unexcreted medicament than are freshly inoculated organisms of the same strain.*

The duration of the period of temporary cure, before relapses occur, can be greatly prolonged by repeated injections of trypanocidal agents. These effects are probably due to injury of proliferating mechanism of the trypanosomes, to the production of immunity and increase of tolerance of the body cells to trypanotoxins. Finally, however, the organisms may develop a "resistance" or "fastness" to the compound and produce fatal relapses despite treatment unless an unrelated drug is employed.

Of considerable interst in this connection is the condition where the trypanosomes may be found during the temporary periods of latency in untreated infections of guinea-pigs and rabbits and more especially in rats and mice treated with substerilizing doses of trypanocidal agents, when organisms are not to be found in the blood. It is generally stated that trypanosomes are to be found in the spleen and bone marrow under these conditions.

In my experiments rats were treated with subcurative doses of arsphenamin, neoarsphenamin and tartar emetic about two days after infection and at a time when the blood contained large numbers. For three or more days following none were to be found in the blood and during this period animals were killed and emulsions of the brain, spleen, liver and bone marrow prepared. These were injected into normal rats intraperitoneally and the animals examined daily for 17 days. The results showed that during latency trypanosomes may be present in the blood and internal organs, especially the liver, spleen and bone marrow.

Vaccines in the Prophylaxis and Treatment of Trypanosomiasis.—In connection with this subject of immunity in trypanosomiasis, it may not be amiss to briefly discuss the subject of active immunization. To the best of my knowledge vaccines have not been employed for prophylactic or curative purposes on a large scale, although they are not difficult to prepare and would possess great value in the prevention of trypanosomiasis of human beings and the lower animals if it could be shown that their administration was followed by the production of antibodies and immunity.

Judged by the clinical course of trypanosomiasis, little or nothing is to be expected, however, from vaccine prophylaxis and treatment. In trypanosomiasis of human beings, as well as in experimental infections of guinea pigs and rabbits, the progress of the disease is sufficiently tardy to permit the development of curative immunity if the body cells were able to bring this about; since, however, the living trypanosomes are unable to engender this immunity, the chances are slight that a vaccine of dead parasites would be more antigenic.

I have immunized rabbits over a period of three to four months with weekly doses of a vaccine of *Tr. equiperdum* by intravenous injection and studied the blood of each animal after each injection for agglutinins, alexo-fixagins and trypanolysins. These doses ranged

from approximately 1,000,000 to 5,000,000 dead trypanosomes per animal (average weight 1500 grams). At the end of the period of immunization each animal was infected with *Tr. equiperdum* and the development of trypanosomiasis compared with infected controls. The sera of these immunized animals was also employed in the treatment of rats infected with *Tr. equiperdum*. The results are summarized as follows: (1) Vaccines engender but slight amounts of agglutinins and complement-fixing antibodies; (2) Vaccines produce but small amounts of trypanolysins; (3) Rabbit immune sera possess but slightly greater protective and curative properties than normal rabbit sera and (4) Immunized rabbits were but slightly more resistant to infection with *Tr. equiperdum* than normal rabbits.

These experiments indicate, therefore, that vaccines of *Tr. equiperdum* engender but slight degrees of immunity. It is possible that living trypanosomes would prove more antigenic, but owing to the extreme susceptibility of animals to virulent strains, immunization of this kind would prove dangerous. Terry has recorded the rather high and very specific nature of the immune sera of goats infected with strains of *Tr. evansi* and serum has been employed by numerous investigators in the treatment of experimental trypanosomiasis of the lower animals. The fundamental reason for failure of vaccine prophylaxis of trypanosomiasis is probably that in this, as in other protozoan infections, immunity and resistance develop slowly and tardily, if at all, in immunization with *dead* parasites. In syphilis vaccines of dead spirochetes are likewise but feebly antigenic; immunity in syphilis requires in the tissues the presence of living spirochetes, although they may be so few and latent that symptoms are not present. Almost the same phenomenon is seen in tuberculosis; apparently only living tubercle bacilli are capable of exciting allergic sensitization of the tissues and vaccines of non-virulent but living bacilli yield best results in immunization. Apparently the same is true of trypanosomiasis; only the living parasites appear capable of producing sufficient antigenic stimulation to engender an immunity and this process is greatly aided and hastened by the administration of a trypanocidal substance, as if the antigenic substance is derived from the lysis of the bodies of the trypanosomes, this process being aided by bringing about their death in the living animal followed by dissolution of the dead parasites by means of autolytic or serum-enzymes. With human beings as with the lower animals, recovery from infection with virulent trypanosomes is not to be expected without medicinal aid, and for this reason the development of a successful method of medicinal treatment is imperative.

Influence of Drugs upon Antibody Production by Vaccines in Trypanosomiasis.—One theory of the mechanism of the curative action of arsphenamin, neoarsphenamin and mercury in syphilis is that these compounds stimulate the body-cells to produce antibodies which are destructive for the spirochetes rather than the reduction-products of the compounds themselves. Naturally this theory is given considerable weight by the immunity following the cure of trypanosomiasis discussed above. As mentioned in the preceding chapter on the mechanism of the trypanocidal activity of organic arsenical and antimony compounds in trypanosomiasis, there is no evidence to show that the death of the trypanosomes is brought about by antibodies rather than by the reduction-products of the compounds themselves when a single curative dose of the drug is given. Under these conditions trypanocidal activity is due to the drugs—if not directly by the drugs as injected, then at least by new compounds produced by their reduction or oxidation in the tissues—because cure is brought about altogether too quickly to afford time for the production of immune substances. However, as will be shortly discussed, when trypanocidal drugs are given in divided doses, there is reason for believing that the resulting cure is aided by immune processes.

In connection with the experiments summarized above on the production of immunity in rabbits by injections of a vaccine of *Tr. equiperdum*, exactly similar tests were conducted at the same time in which the rabbits were injected with the same vaccine in the same way and at the same time received intravenous injections of 0.010 gm. arsphenamin and 0.015 gm. neoarsphenamin per kilo of weight to determine if these compounds would aid and increase the production of antibodies and immunity. Exactly the same tests for agglutinins, alexo-fixagins and trypanolysins were conducted; after twelve injections of vaccine and drug the results were identical with those summarized above in the case of rabbits receiving only the vaccine. The animals were also finally infected with living trypanosomes as described above, and the appearance of trypanosomes in the blood and the appearance of symptoms and lesions of trypanosomiasis occurred in practically the same time and manner as among the rabbits receiving only the vaccine. These experiments showed that the drugs (administered in the usual therapeutic doses employed for the treatment of syphilis) were without the slightest effect in aiding the production of demonstrable antibodies in the serum when administered along with a dead vaccine.

In other words *the administration of these drugs does not aid in the production of immune substances and immunity when administered along with dead vaccines; they do, however, aid in the production of immunity and cure when administered during the course of trypanomiasis*, as shown by the immunity in relapses and following cure. For this reason it is highly probable that in the treatment of trypanosomiasis the cure that follows a single large dose of trypanocidal agent is brought about by the drug itself; but in cures brought about by the administration of divided doses, cure is aided by the production of immunity principles.

CHAPTER XVIII

COMPARATIVE STUDY OF METHODS FOR THE ADMINISTRATION OF TRYPANOCIDAL COMPOUNDS IN RELATION TO THE CHEMOTHERAPY OF TRYPANOSOMIASIS

In the preceding chapters bearing upon the chemotherapy of experimental trypanosomiasis, the relative values of the different drugs were largely expressed upon the basis of single maximum tolerated and single minimal curative doses per kilogram of body weight. In the majority of instances the compounds were administered by intravenous injection in order to secure as decisive results as possible, and acute infections of mice and rats were employed to a greater extent than chronic infections of rabbits. The results are of great value not only in the interests of the advancement of the pure science of chemotherapy, but also because the data obtained is applicable in a broad and general manner to the treatment of trypanosome diseases of human beings and the lower animals. It is true, as will be shortly discussed, that in the treatment of chronic trypanosomiasis the questions of penetration

of the medicament into the lesions, as well as the modifying influences of rate or excretion, debilitated condition of the host and pathological changes in the various tissues and organs, require due consideration, but in a general way those medicaments yielding the best chemotherapeutic indices in acute trypanosomiasis are also most likely to yield best results in chronic infections and particularly if they may be given by intramuscular and subcutaneous injection as well as intravenously.

Limited Value of Therapie Magna Sterilisans in Trypanosome Diseases. While it is true that single large doses of various trypanocidal compounds are curative for the acute and even chronic experimental trypanosome infections of the mouse, rat and rabbit, yet this method has a very limited application in the treatment of African trypanosomiasis of human beings and natural iinfections of the lower animals. It is only exceptionally in human beings that treatment is undertaken sufficiently early after infection to hold out hope for complete cure with a single dose of drug; in the great majority of instances the lymphatic glands and other tissues are already involved, even though the spinal fluid shows no changes of increased cells and proteins. Single large doses may clear the blood stream, but relapses are likely to occur. Even under the most favorable conditions when treatment is possible soon after infection, the majority of physicians would hesitate to administer the doses required, as indicated by the results of animal experiments. For example, the single minimal curative dose of tryparsanid for rabbits within 5 to 10 days after infection with *Tr. gambiensi* would be about 0.2 gm. per kilogram; this is equivalent to 12 grams for a 60 kilogram adult (about 130 pounds), but one would naturally hesitate to administer a single dose of this size either by intravenous or intramuscular injection, even though the subject were in good general condition. A much better plan would be the administration of smaller amounts at intervals sufficiently close that an injection is given before the curative effects of the former treatment have ceased. *Therapie magna sterilisans* is possible under experimental conditions but rarely in natural trypanosome diseases.

Application of the Results of the Chemotherapy of Experimental Trypanosomiasis to the Treatment of Trypanosome Diseases of Man and the Lower Animals.—The results observed in the chemotherapy of experimental trypanosomiasis have, however, a direct application in the treatment of trypanosome diseases of human beings and the lower animals to the extent that compounds possessing the highest chemotherapeutic indices in experimental infections are most likely to be efficacious and to be preferred.

Unfortunately, however, data regarding dosage in the chemotherapy of experimental trypanosomiasis is not directly applicable to human beings or even the lower animals with trypanosome diseases. While body weight is a much better guide than age for regulating dosage, it is lacking in accuracy and tolerance bears no direct relation to weight. While in the acute infections of mice and rats there do not enter the modifying factors of pathological changes and lesions of the fixed tissues and organs together with debilitation and poor general conditions which are so important in the treatment of natural trypanosome diseases, yet these changes can be quite successfully duplicated by employing experimental infections of rabbits with such virulent organisms as *Tr. brucei*, *Tr. gambriensi* and *Tr. equiperdum.* Indeed, in the rabbit these modifying factors may be created more or less at the will of the investigator and may reach a greater degree of severity than ordinarily encountered in natural infections.

Animal experimentation in trypanosomiasis has, therefore, a very direct and valuable application to the treatment of natural trypanosome diseases.

Indeed, the application is even wider, because with some trypanocidal medicaments, and particularly arsphenamin and neoarsphenamin, the results are applicable for the laying down of principles for the treatment of human syphilis.

Confusion Regarding Dosage, Intervals and Route of Administration of Trypanocidal Compounds.—In relation to the very important questions of dosage, frequency and route of administration of medicaments in the treatment of trypanosome diseases, experimental chemotherapy furnishes data of direct value and application.

In the treatment of human trypanosomiasis and syphilis the greatest divergence of opinion and practice can be found among experienced physicians regarding the size of the dose, the frequency and route of administration, to mention nothing of the selection of medicament or the question of using two or more medicaments as a combination therapy. Whether the medicaments should be given once a week, twice a week, daily for three doses or daily for six doses, etc., are questions of debate and each plan has been endorsed by various physicians so that great confusion exists regarding the best course to pursue. Of course, a large number of factors require consideration, among which may be mentioned the questions of toxicity, the stage of the disease, the route of administration, the rate of absorption and elimination of the medicament and the rapidity with which a compound is rendered therapeutically active in the body after administration, granting that pentavalent compounds like atoxyl first require reduction and that trivalent compounds like arsphenamin and neoarsphenamin are not of themselves trypanocidal or spirocheticidal but first require oxidation in the body.

The therapy of relapses in both trypanosomiasis and syphilis of human beings constitutes the greatest problem in treatment. The treatment of acute early infections offers no difficulties; the principles are fairly well understood and the results generally excellent. But in relapses a chronic infection is present in which the questions of possible acquired resistance or fastness of the parasites to drugs require consideration, as likewise the even more important modifying factors of penetrability of the drug into the diseased tissues, the toxicity of the medicament for already damaged tissues and organs and the general health and condition of the subject. But here again these conditions may be duplicated in the lower animals and especially the rabbit, both in trypanosomiasis and syphilis. It requires, however, that the experimental chemotherapeutist shall treat each rabbit as an entity rather than as one of a group since treatment should be planned for each individual as a separate problem.

The employment of rabbits in experimental trypanosomiasis and syphilis affords not only a means for selecting the best medicament and deciding on the questions of size and frequency of dosage, but also the route of administration, concerning which much difference of opinion exists among physicians. With these general considerations in mind, I have conducted a large series of investigations for the purpose of eliciting data of practical value regarding dosage, frequency and route of administration of the more important trypanocidal compounds in the treatment of acute and chronic trypanosomiasis. While these results are more directly applicable to the treatment of trypanosome diseases of man and the lower animals, I believe that they are likewise applicable to the treatment of syphilis and especially with the organic arsenical compounds of the arsenobenzol group, since a fairly close relationship between their trypanocidal and spirocheticidal properties has been demonstrated.

Methods of Administration in Relation to the Treatment of Acute Trypanosomiasis of the Rat.—In conducting these experiments white rats were infected with *Tr. equiperdum* and treatment started 24 hours later according to the technic of my method described in Chapter X. These conditions were most favorable for the medicament, as the blood invasion had just begun when treatment was instituted.

Results with Arsphenamin.—The single minimal curative dose of the arsphenamin employed was 0.004 gm. per kilogram of weight corresponding to 0.28 gm. per 70 kilograms. This amount yielded 100 per cent. cures; 100 per cent. cures were also observed with the following:

3 daily intravenous injections of 0.003 gm. per kilo.
6 daily intravenous injections of 0.002 gm. per kilo.
5 twice weekly intravenous injections of 0.0026 gm. per kilo.
6 weekly intravenous injections of 0.0026 gm. per kilo.

In other words, when three daily doses were given, the amount required was three quarters of the single minimal curative dose; 6 daily doses required one half the minimal curative amount in each while in weekly and twice weekly methods of administration multiple doses of two thirds the single minimal curative dose were required.

Results with Neoarsphenamin.—The minimal curative dose of the neoarsphenamin employed was 0.006 per kilogram; this single dose yielded 100 per cent. cures. Similar results were observed with the following:

3 daily intravenous injections of 0.005 gm. per kilo.
6 daily intravenous injections of 0.0045 gm. per kilo.
4 twice weekly intravenous injections of 0.005 gm. per kilo.
8 weekly intravenous injections of 0.005 gm. per kilo; cured 50 per cent. of animals.

It will be noted that, when multiple doses of neoarsphenamin were administered, at least three quarters of the single minimal curative dose was required when the injections were given on three to six days consecutively or twice weekly. When the injections were given once per week, almost the minimal curative dose was required because the effects of the compound were much shorter than observed with arsphenamin and the few organisms escaping destruction multiplied so rapidly as to destroy the lives of about 50 per cent. of the animals before the next injection could be given.

Results with Atoxyl.—The minimal curative dose of the compound employed in this study was 0.060 gm. per kilogram, the maximum tolerated dose being 0.150 gm. As a general rule, the administration of 0.060 to 0.080 gm. per kilogram resulted in 100 per cent. of cures. Multiple doses yielded the following results:

3 daily intravenous injections of 0.040 gm. per kilo.
6 daily intravenous injections of 0.030 gm. per kilo.
4 twice weekly injections of 0.050 gm. per kilo; cured about 40 per cent. of animals.
6 weekly injections of 0.050 gm. per kilo.; cured about 20 per cent. of animals.

These results have shown that best results with divided doses of atoxyl were observed with the 3 to 6 daily dose plan, the amounts required being about one half of the single minimal curative dose. With the twice weekly and weekly plans the surviving organisms were frequently able to proliferate so rapidly as to destroy the rats before the succeeding dose was due.

A general result of this study was to show that in the treatment of acute trypanosomiasis of the rat in which the death of untreated controls occurred on the fifth to sixth day after inoculation with *Tr. equiperdum*, best results with divided doses were observed when the treatments were given for three to six days consecutively. *If these results have an application to the treatment of acute trypanosomiasis and syphilis of human beings in the earliest stages of these diseases, it would be to indicate that, when a single curative dose cannot be given, best results occur when smaller doses are given intensively, that is, by intravenous injection for three to six days in succession.*

Methods of Administration in Relation to the Treatment of Chronic and Relapsing Trypanosomiasis of the Rabbit.—With rabbits information of greater practical value relating to route of administration, frequency and size of dosage may be obtained since rabbits infected with *Tr. brucei*, *Tr. equiperdum* or *Tr. gambiensi* develop chronic lesions of the skin, face, genital organs, etc., bearing a close similarity to the lesions of natural trypanosome

diseases of human beings and the lower animals. In rabbits, however, the disease pursues a more rapid course than in human beings, but they present the same problems of penetrability or medicament, fastness of parasite, general debility of host, etc., as encountered in natural infections.

In conducting these therapeutic experiments, treatment was begun about three weeks after infection and at a time when the majority of animals showed well-advanced tissue changes, loss of weight and general debility. After treatment the animals were kept under observation for four months or longer and relapses treated as they developed.

The single curative dose of *arsphenamin* by intravenous injection for chronic *Tr. equiperdum* infections of rabbits is about 0.020 gm. per kilogram. Smaller doses suffice for dissipating the lesions and symptoms for variable periods, but relapses generally occur some weeks later. This dose corresponds to 1.2 gm. per 60 kilograms or about 130 pounds, the average weight of an adult.

With divided doses best results were observed when the treatments were given daily for at least three days in succession. With this plan three daily doses of about 0.010 gm. per kilogram were sufficient. When the compound was administered twice weekly, the amount required was from 0.010 to 0.015 gm. per dose for at least two to four doses. When given once a week, almost the full dose was required. Rabbits treated with a dose of 0.010 gm. per kilogram once a week frequently relapsed after three to four doses; the weekly injection of 0.015 gm. per kilo for at least three consecutive weeks generally results in complete cures.

In the treatment of relapses larger amounts were required. Rabbits relapsing two to seven weeks after the injection of 0.005 gm. per kilogram required single doses as high as 0.030 gm. per kilogram to effect a complete cure, or at least three daily doses of about 0.015 gm. per kilogram.

One result of these tests was to show that, when single large doses were contraindicated on account of the extreme loss in weight and debility of the animals, best results were secured by giving smaller amounts at daily intervals for two or three doses; next best results were observed with twice-weekly injections. Under these conditions, the effects of a dose had hardly worn off before re-enforced with the succeeding dose and in this manner sterilization was accomplished without signs or symptoms of toxicity.

Similar results were observed with *neoarsphenamin*, except that larger amounts were required. However, the weekly injections were less successful; likewise, the twice-weekly plan of treatment. Neoarsphenamin is eliminated more rapidly than arsphenamin; at least, its trypanocidal effects are of shorter duration. Daily doses yield excellent results, but with weekly doses surviving trypanosomes are able to proliferate rapidly unless relatively large amounts are given.

The single curative dose for rabbits is about 0.030 to 0.040 gm. per kilogram. Smaller amounts were sometimes curative, but relapses occurred in some animals. Three daily doses in succession of 0.015 gm. per kilogram were generally curative; likewise the twice-weekly injection of 0.020 gm. per kilogram for at least three doses. When the injections were given once a week, doses of 0.010 gm. per kilogram were generally followed by relapses; doses of 0.020 to 0.030 gm. were generally required for effecting complete cures.

Relapses required larger amounts as was found with arsphenamin. Rabbits relapsing three to nine weeks after the injection of 0.005 to 0.010 gm. arsphenamin or neoarsphenamin per kilogram, required single doses of about 0.040 gm. neoarsphenamin for permanent cures or three to four daily doses of about 0.015 to 0.020 gm. per kilogram.

The results observed with *atoxyl* were not so satisfactory, as many animals succumbed before the experiments were completed. The single curative dose by intravenous injection was about 0.050 to 0.080 gm. per kilogram, but these amounts frequently produced fatal intoxication in view of the debilitated condition of the animals. The advantages of smaller doses repeated at close intervals were strikingly apparent; daily injections of 0.020 gm. per kilogram for three to five doses in succession were generally curative, with only exceptional deaths due to toxicity. When given twice weekly at least 0.040 gm. per kilogram was required for three to six doses. Weekly injections generally failed, unless the amount given approached in size the single curative dose which was frequently toxic.

Sulpharsphenamin by subcutaneous or intramuscular injection yielded splendid results. The single curative dose varied from 0.020 to 0.040 gm. per kilogram. Daily doses of 0.010 gm. per kilogram yielded good results when at least three were given in succession. Twice-weekly injections of 0.020 gm. per kilogram and weekly doses of 0.030 gm. per kilogram yielded results equal in curative activity to those observed with arsphenamin and very much better than with neoarsphenamin. In these amounts there were no symptoms of intoxication and in the majority of instances no local reactions at the site of injection beyond small areas of temporary induration. The therapeutic effects of a dose were slightly more prolonged than observed with arsphenamin and much more than with neoarsphenamin, due, probably, to slower absorption and elimination.

Rabbits commonly relapsed after single doses of 0.005 to 0.010 gm. per kilogram. Treatment of these required larger amounts, the single curative dose being about 0.040 gm. per kilogram or three to four daily consecutive doses of 0.015 to 0.020 gm. per kilogram.

Excellent results were likewise observed with *tryparsamid*. The single curative dose by intravenous injection was about 0.4 to 0.6 gm. per kilogram of weight; by intramuscular injection the curative dose was practically the same (0.5 to 0.6 gm. per kilogram).

Three daily intravenous or intramuscular injections of 0.2 gm. per kilogram were generally curative, relapses occurring only twice in a series of six animals; three daily doses in succession of 0.1 gm. each dissipated the lesions temporarily, but relapses generally followed about four weeks later. Twice-weekly doses of 0.3 gm. each for two to five injections were curative; with 0.2 gm. per kilogram relapses occurred. Weekly injections of 0.3 for two to six weeks were likewise curative.

Relapses following previous treatment with atoxyl, arsphenamin and neoarsphenamin generally required a single dose of about 0.6 gm. per kilogram or four daily consecutive doses of 0.2 gm. per kilogram.

With tartar emetic single doses required as much as 0.020 to 0.040 gm. per kilogram by intravenous injection and many rabbits succumbed a few days later as the result of toxic effects. The maximum tolerated dose for healthy normal rabbits was about 0.050 to 0.060 gm. per kilogram, but tolerance was reduced by chronic trypanosomiasis. The advantage of giving smaller doses at frequent intervals was strikingly shown in these experiments. Three to four doses of 0.015 to 0.020 gm. per kilogram by intravenous injection daily in succession produced complete cures in most instances; occasionally an animal relapsed, but none were lost by toxic effects. Twice-weekly injections of 0.020 to 0.040 gm. per kilogram were likewise generally successful when at least three doses were given. Weekly doses generally failed unless almost the single curative dose was given, in which case many animals died within a few days of toxic effects.

Principles of the Chemotherapy of Acute and Chronic Trypanosomiasis.—These experiments have shown that in the treatment of acute trypanosomiasis single large curative doses may be given with success, because tolerance has not been greatly reduced by infection. Since this practice is not usually permissible in the treatment of human beings, the administration of smaller amounts at daily intervals or at intervals of two or three days for several doses in succession have yielded best results. Under these conditions there does not appear to be accumulative toxic effects and the parasites are attacked vigorously over a short period of time with rapidly succeeding doses. "Hitting hard" for a brief period has yielded better results in acute infections than milder treatment by longer intervals between doses, and owing to the good general condition of the subjects the danger of toxic effects is reduced to a minimum.

In the treatment of chronic infections single large doses may produce toxic effects owing to the reduced vitality of the subjects. This is especially true of compounds with relatively low chemotherapeutic indices, that is, the minimal curative doses being but two to four times less than the tolerated or toxic amounts. In chronic infections the administration of smaller doses, at intervals of one to three days for several doses in succession, have yielded best results. Under these conditions the effects of one dose have hardly worn off before the parasites are attacked by a succeeding dose and rapid elimination tends to prevent cumulative toxic effects. When compounds are given intramuscularly, such as atoxyl, tryparsamid and sulpharsphenamin, the doses should be a little larger than by intravenous injection, but the intervals may be lengthened to three or four days or even a week.

Repeated small doses, administered at intervals sufficiently close that the effects of the preceding dose have not entirely disappeared before the succeeding dose is given, permits the compound to penetrate the chronic inflammatory exudates, is especially useful when the general condition of the host is poor and debilitated, is least likely to produce toxic effects and is the method of choice in the treatment of chronic infections. Under these conditions the proper spacing of the injections is almost as important as the number and size of the doses. I

believe that these principles apply in the treatment of acute and chronic syphilis as well as in acute and chronic trypanosomiasis, but further discussion of the subject in reference to syphilis with similar experiments in spirochetic infections of rabbits is given in Chapter XXIX.

A combination of two or more trypanocidal agents may be more effective in the treatment of African trypanosomiasis or infections of the lower animals, than treatment with a single compound, but I shall discuss this phase of the chemotherapy of trypanosomiasis in the succeeding chapter (Chapter XIX).

Intramuscular versus Intravenous Administration of Trypanocidal Compounds.—This route of injection of trypanocidal compounds is a subject of considerable practical importance in the treatment of trypanosomiasis. This is particularly true in Africa where conditions are such that subcutaneous or intramuscular injections are more easily given than intravenous injections and especially on a large scale.

Aside from this question of convenience, however, the subject is of great interest in relation to the principles of chemotherapy and to the treatment of syphilis. In the acute early stages of both trypanosomiasis and syphilis when the parasites are in the lymph and blood, intravenous injections would appear to be indicated, but as soon as the blood has been sterilized, intramuscular or subcutaneous injections may yield better therapeutic results, inasmuch as absorption and elimination are slower, with the result that medicaments are longer retained and may thereby better penetrate inflammatory exudates and reach the parasites in chronic lesions.

The question, therefore, becomes one largely of absorption and elimination and is discussed with more detail in Chapter XXIX, devoted to a discussion of these subjects in relation to the treatment of syphilis. Here may be mentioned the work of Voegtlin and Thompson[1] who found that the excretion of different arsenicals varied after intravenous injection, the directly toxic trivalent oxid compounds showing the slowest rate, the pentavalent arsenicals the fastest, and the arsenobenzene compounds occupying an intermediate position. Elimination of arsenic was found to vary among different individuals of the same species of animals and constituted the chief factor responsible for differences in toxicity and trypanocidal activity. Voegtlin and Smith[2] found that, so far as arsphenamin and neoarsphenamin are concerned, intramuscular injections were just as curative as intravenous injections in the treatment of trypanosomiasis of rats. Unfortunately, however, neither compound can be employed by intramuscular injections in the treatment of human subjects because of the local pain, unless small doses are given in oil, but the principle of the intramuscular route of administration in the treatment of chronic trypanosomiasis and syphilis is based upon sound principles and this route is to be preferred after the blood has been sterilized of parasites, providing intramuscular injections can be borne by patients. This is true of atoxyl, which is largely given in Africa by subcutaneous injection, and it is very much hoped that more powerful trypanocidal agents like sulpharsphenamin will be produced, which may be repeatedly injected subcutaneously or intramuscularly in adequate doses for the treatment of human trypanosomiasis.

CHAPTER XIX

COMBINATION TREATMENT OF EXPERIMENTAL TRYPANOSOMIASIS AND ITS BEARING UPON THE PRINCIPLES OF CHEMOTHERAPY

A combination of compounds in the chemotherapy of trypanosome and spirochetic infections had always engaged the interest and attention of Ehrlich. Parasites may become resistant to one drug while retaining susceptibility to others. Furthermore, important reactions *in vivo*, probably involving the colloidal state of compounds in the blood and other body fluids, may modify toxicity of the compounds alike for both body cells and parasites. Thus Kolle[1] has recently stated that, contrary to usual impressions and expectations, the simultaneous intravenous injection of a soluble mercurial compound and arsphenamin does not increase toxicity of either compound for the host; on the contrary, toxicity for the host is usually reduced, while parasiticidal activity is actually greater than would be expected from a mere summation of the effects of each compound separately. In this connection it may be mentioned that Browning[2] observed that the treatment with arsacetin and trypan-blue of mice infected with *Tr. brucei* yielded better results than treatment with either compound alone.

Increased Therapeutic Activity of Arpshenamin and Neoarsphenamin in Combination with Mercury.—According to Kolle the toxicity of mercury is reduced in mixtures with arsphenamin because the latter serves, so to speak, as a protective colloid for the colloidal mercury. Arsphenamin derivatives containing a formaldehyd sulphoxylate group are to be preferred in his opinion, because they possess points of attack for the oxidizing mercurial compounds in the formaldehyd group and thereby effect a derivation of the mercury from the arseno group. Since the mercurial preparations enter into a reciprocal action with the arsphenamin compound, whereby the latter is partly changed, and as nearly all mercurials possess an oxidizing power, it is well to employ mercurials of weak oxidizing activity, since arphenamin is a strongly reducing compound and it is advisable in the mixtures to keep the arseno group as intact as possible. From this standpoint mercuric chlorid was found less suitable by Kolle than a new mercurial compound designated as "novasurol."

In this connection I may summarize the experimental work of Neisser[3] in the treatment of syphilis of monkeys with mercury salicylate and atoxyl, although, since these were not always injected together but separately (although at the same time), the effects are not exactly similar to the administration of two compounds in the same solution. Four animals, injected subcutaneously with 0.040 gm. of mercury salicylate and 0.6 gm. of atoxyl per animal (2 to 6 kilos) at the time of inoculation with virus, escaped infection. Of nine additional monkeys injected with 0.040 gm. of mercury salicylate and 0.2 gm. of arsacetin, eight escaped. Of eighteen animals treated with 0.04 to 0.06 gm. of the salicylate and 0.2 to 0.9 gm. of atoxyl after the development of primary lesions, twelve and possibly fourteen, were cured. Of ten monkeys treated with 0.008 to 0.076 gm. of mercuric arsanilate (Uhlenhuth's atoxyl-mercury compound) per kilogram, six were probably cured (in three re-inoculation was negative indicating no cures and in one, spirochetes persisted in the lesions).

Toxicity and Trypanocidal Activity of Mixtures of Solutions of Arsphenamin, Neoarsphenamin and Mercurophen.—As mentioned in Chapter XIV, organic compounds of arsenic and mercury have not so far proven of much value in the treatment of trypanosomiasis, but I have considered it worth while to continue investigation along these lines by studying mixtures of solutions of arsphenamin, neoarsphenamin and various soluble salts of mercury. In chronic syphilis especially, a system of combination treatment with both arsphenamin and a mercury compound administered simultaneously may yield better results than either alone, as discussed in Chapter XXX.

Solutions of most salts of mercury are not suitable for mixture with arsphenamin and neoarsphenamin. Solutions of the bichlorid, benzoate, cyanid, oxycyanid, succinimid and cacodylate, when added to alkalinized solutions of arsphenamin or solutions of neoarsphenamin in water, yield dark, yellowish-green mixtures with the formation of precipitates. Solutions of mercurophen (sodium oxy-mercuri-ortho-nitro phenolate) in water added to solutions of arsphenamin or neoarsphenamin are, however, usually perfectly satisfactory for at least twenty-four hours and for longer periods if sealed in vacuum; some lots of mercurophen, however, may produce slightly opalescent mixtures. Linsser however, administers intravenously the dark greenish mixture of mercuric chlorid and neoarsphenamin in the treatment of syphilis (see page 353).

Trypanocidal tests with these mixtures have yielded very interesting results. White rats infected with *Tr. equiperdum* were employed according to the technic of my method. In one experiment an alkalinized solution of arsphenamin was trypanocidal in dose of 0.003 gm. per kilo; when mixed with 0.002 gm. of mercurophen per kilo, the trypanocidal dose of the arsphenamin was reduced to 0.0015 gm. per kilo; and when mixed with 0.001 gm. mercurophen, the dose was still further reduced to 0.001 gm. Mercurophen itself had no demonstrable trypanocidal effects in the amounts employed, namely, 0.002 and 0.001 gm. per kilo. In an experiment with neoarsphenamin, the smallest trypanocidal dose was found to be 0.008 gm. per kilo. When 0.002 gm. of mercurophen per kilo was added and injected, the trypanocidal dose of the neoarsphenamin was reduced to 0.005 gm. per kilo; when 0.001 gm. of mercurophen was added, the trypanocidal activity of the neoarsphenamin was reduced to 0.004 gm. per kilo.

Additional experiments with other lots of arsphenamin and neoarsphenamin yielded essentially similar results and have shown that the trypanocidal activity of arsphenamin and neoarsphenamin is sometimes, but not always, enhanced by the addition of sub-toxic amounts of mercurophen. Somewhat similar results have been observed in the treatment of rabbit syphilis, described in Chapter XXX.

The maximum tolerated dose of mercurophen by intravenous injection into rats is approximately 0.008 gm. per kilo; the doses employed, therefore, were one-fourth and one-eighth this amount. Toxicity tests, conducted by injecting rabbits intravenously twice a week with 0.020 gm. arsphenamin and 0.001 gm. mercurophen per kilo, have shown no ill effects after as many as eighteen of the combined injections; these amounts corresponded to 1.2 gm. arsphenamin and 0.060 gm. (1 grain) of mercurophen respectively, per 60 kilograms or the weight of an adult human being.

Trypanocidal Activity of Mixtures of Solutions of Arsphenamin and Flumerin, and of Solutions of Neoarsphenamin and Flumerin.—As stated in Chapter XXIV *flumerin*, disodium hydroxy-mercuri fluorescin, prepared by White, Hill, Moore and Young, is a remarkable compound from the standpoint of low toxicity, since it contains about 32.5 per cent. of mercury and is tolerated by rats and rabbits in amounts of 0.030 to 0.040 gm. per kilogram by intravenous injection. *Mercurophen* contains from 46 to 50 per cent. mercury and is tolerated in dose of about 0.006 to 0.008 gm. per kilogram, so that while the mercury content of *flumerin* is 1.5 times less than in mercurophen, its toxicity is about 5 times less, showing that in terms of pure mercury *flumerin* is considerably less toxic than mercurophen.

Mixtures of 0.5 per cent. disodium solutions of arsphenamin and 2 per cent. solutions of *flumerin* in proportion of 10:1 showed no color changes or separation of mercury in six hours at room temperature, but after standing eighteen hours metallic mercury had separated out from the solution. Mixtures of 10 per cent. solutions of neoarsphenamin in water with 2 per cent. solutions of flumerin in proportion of 2:1 likewise showed no color or other visible changes in periods up to six hours at room temperature, although after eighteen hours some metallic mercury had separated from the solution. It was easily possible, therefore, to mix solutions of flumerin and arsphenamin or neoarsphenamin and administer by intravenous injection any time during the first six to ten hours.

In a series of trypanocidal tests employing *Tr. equiperdum*, flumerin was found without appreciable curative activity in single doses as high as 0.030 gm. per kilo administered twenty-four hours after infection. However, when added in amounts of 0.005 to 0.010 gm. per kilogram to solutions of arsphenamin and neoarsphenamin, the trypanocidal activities of the latter were slightly increased. For example, a dose of 0.001 gm. arsphenamin per kilo restrained the appearance of trypanosomes in the peripheral blood for four days after inoculation, but did not prove curative; this dose plus 0.010 gm. of flumerin per kilo, however, restrained the development of trypanosomiasis for ten days. Neoarsphenamin in dose of 0.002 gm. per kilogram restrained trypanosomes for eight days, but was not curative; this dose plus 0.010 gm. of flumerin restrained the infection for sixteen days. These results are, therefore, similar to those observed with mercurophen and indicate that amounts of flumerin without demonstrable trypanocidal activity are capable of appreciably increasing the trypanocidal activity of arsphenamin and neoarsphenamin. The addition of 0.001 to 0.002 gm. of flumerin per kilogram of weight to the doses of arsphenamin and neoarsphenamin did not increase trypanocidal activity and, curiously, a dose of 0.020 gm. of flumerin added to the solutions of arsphenamin and neoarsphenamin was likewise without appreciable effect; indeed, this dose apparently increased the severity of infection probably by reducing resistance through toxic effects upon the host.

Trypanocidal Activity of Arsphenamin and Neoarphenamin in Combination with Tartar Emetic, Sodium and Potassium Tartro-bismuthate, Tryparsamid, Mercurophen, Trypan-red and Trypan-blue.—In view of the results of these experiments, showing that mixtures of arsphenamin and neoarsphenamin with the two organic mercurial compounds mercurophen and flumerin, sometimes resulted in producing a greater degree of trypanocidal activity than a summation of curative effects of the respective drugs alone, additional experiments have been conducted with mixtures of arsphenamin and neoarsphenamin with other trypanocidal agents as tartar emetic, sodium and potassium tartro-bismuthate, trypan-red and trypan-blue.

My purpose was to use each drug in about one-fourth of its trypanocidal dose in order to determine if mixtures of two would enhance curative activity. In some instances the development of trypanosomiasis was delayed, and especially by arsphenamin, neoarsphenamin and tryparsamide, but cures were not produced by the doses employed. Mixtures of arsphenamin or neoarsphenamin with tartar emetic, sodium and potassium tartrobismuthate and trypan-red did not show any increase of trynanocidal activity; indeed, the addition of these compounds to solutions of arsphenamin and neoarsphenamin actually hastened the development of trypanosomiasis with lethal results. The only explanation to be offered at this time is that the toxicity of these compounds reduced the resistance of the rats and thereby favored the development of trypanosomiasis.

The addition of tryparsamid, mercurophen and trypan-blue, however, usually resulted in slightly increasing the trypanocidal effects; with tryparsamid these results may have been due to a summation of trypanocidal activities, but with mercurophen and trypan-blue this explanation hardly suffices since the compounds alone in the doses employed were totally without demonstrable curative activity.

Voegtlin and Smith have observed a complementary action of arsenical and antimony compounds and recently Myers and Corbitt[4] have reported that the administration of neoarsphenamin to rats in subeffective dose (0.005 gm. per kilo) by intraperitoneal injection twenty-four hours after treatment with sodium and potassium tartrobismuthate, resulted in prolonging the lives of some animals beyond the time noted with neoarsphenamin alone; the tartrobismuthate alone was without curative effects and the trypanocidal tests were conducted after the method of Voegtlin and Smith.

Chemotherapeutic Significance of Combination Therapy.—The subject of combination therapy is, therefore, full of theoretical and practical interest and importance. Not only may the administration of two compounds of

totally different origin increase parasiticidal effects by a mere summation of the curative activities of each alone, but, as shown by Kolle, it would appear that one compound may enhance the parasiticidal effects of another by physico-chemical changes.

Of course, combination therapy has been used empirically for many years, as, for example, atoxyl and tartar emetic in human trypanosomiasis and arsphenamin or neoarsphenamin with mercury in the treatment of syphilis. The synergistic effects of two or more drugs is the basis for the prescription of several drugs acting in the same way as, for example, several purgatives prescribed together may act more efficiently than any one given in quantity equal to all of them. Likewise a mixture of morphin and chloral is sometimes more efficient than either administered alone in larger dose. From the standpoint of the practical chemotherapy, the whole subject is of considerable importance and especially in relation to the treatment of trypanosomiasis and syphilis.

CHAPTER XX

CHEMOTHERAPY OF TRYPANOSOME DISEASES OF MAN AND THE LOWER ANIMALS

It is not my purpose to mention here the very large number of different substances that have been advocated from time to time in the treatment of trypanosomiasis of human beings and the lower animals; excellent reviews are to be found elsewhere.[1] Rather shall I confine myself to a discussion of the subject from the viewpoint of the pathological changes produced in these diseases and the knowledge gained from more recent chemotherapeutic researches in experimental trypanosomiasis. Regarded from these standpoints, I believe the principles of the treatment of trypanosomiasis of both human beings and the lower animals are essentially similar to those applicable in the treatment of syphilis in its acute and chronic stages, and that a great deal which we have learned regarding the treatment of the latter disease may be applied in principle to the treatment of trypanosomiasis.

Etiology of Trypanosomiasis of Man.—Fortunately, only three or four species of the large number of known pathogenic trypanosomes are capable of infecting human beings. Presumably none of those producing disease in horses, mules, cattle, sheep, camels and other of the lower animals appear capable of infecting man; positive statements, however, cannot be made, because there is no conclusive evidence that human beings are absolutely immune to *Tr. evansi*, *Tr. brucei*, etc. Indeed some investigators regard *Tr. rhodesiensi*, known to produce a form of African trypanosomiasis, as being identical with *Tr. brucei*, the cause of "nagana disease" of horses. It may be stated, however, that trypanosomes are not found in human beings except in disease, that is, non-pathogenic or saprophytic forms are not encountered analogous to *Tr. lewisi* of rats, *Tr. rotatorum* of frogs, etc.

The best known trypanosome disease of man is *African trypanosomiasis*, designated and more familiarly known as "African *sleeping sickness*," owing to the torpor of the later stages of the infection. At least two very closely related trypanosomes are known to be the cause of this disease, namely, *Tr. gambiensi*, transmitted by the tsetse fly (*Glossina palpalis*), and *Tr. rhodesiense*, transmitted by the fly (*Glossina morsitans*). Recently Macfie has described another subspecies: *Tr. nigeriense*, transmitted by *Glossina tachinoides*. The disease, however, produced by these three trypanosomes is essentially similar in its pathological changes and symptoms, although variations in virulence are encountered in different localities as modified by epidemiological factors. The exact relationship of *Tr. rhodesiense* to *Tr. gambiensi*, however, has not been established. When the former is passed through the rat it presents certain morphological differences, although in human blood it is morphologically indistinguishable from *Tr. gambiensi*. While the symptoms of *Tr. rhodesiense* infection are similar to those produced by *Tr. gambiensi*, the febrile paroxysms are more frequent, glandular involvements are usually more severe and the disease generally runs a much more rapid course. According to some observers animals immunized against *Tr. gambiensi* are not protected against *Tr. rhodesiensi* and if the latter is not a distinct species, it is at least a very definite variety producing disease of human beings much more difficult to cure.

A third type of human trypanosomiasis is known as "Chagas' disease" caused by *Tr. cruzi*, transmitted by a bug, the *Conorhinus megistus*. This disease has been found in Brazil and Venezuela and is sometimes designated as "American trypanosomiasis." The armadillo is supposed to be the natural reservoir of this trypanosome, 50 per cent. of the animals being infected. In Venezuela the intermediate host is *Rhodnius prolixus*.

More recently Escomel reports the discovery of a human trypanosome in Peru, which Yorke considers a distinct species (*Tr. escomeli*).

The Nature and Pathology of African Trypanosomiasis in Relation to Chemotherapy.—African trypanosomiasis in its early stages is essentially an infection of the lymphatic system and to some extent of the blood; later the tissues are involved and especially those of the central nervous system. In these respects the disease is similar to syphilis in that the lymphatic system is likewise early invaded by *Sp. pallida* accompanied by early spirochetemia with later involvement of the fixed tissues and especially of the central nervous system.

The period of two to three weeks primary incubation in trypanosomiasis, the degree of local irritation of greater or less severity at the site of the bite of an infected *Glossina* noted in some cases, the irregular fever, debility, early polyadenitis, slight anemia and papular eruptions which may continue for months are additional clinical features bearing some similarity to those found in syphilis. The local edemas of human trypanosomiasis, which are likewise characteristic of the experimental disease in rabbits, is a special feature due to the embolic blocking and endothelial hyperplasia of lymphatic channels by the large trypanosomes. Doubtless if *Spirochæta pallida* were larger, similar lesions would develop in human and experimental syphilis more frequently than encountered.

The development in trypanosomiasis of *irido-cyclitis* and *choroiditis* with gradual involvement of other special organs and more particularly the brain, bears a close similarity to the course of syphilis. The psychical and physical symptoms of the former are usually different from those developing in syphilis, because vascular occlusion due to endothelial hyperplasia is frequent, the parasites are larger and the infection usually numerically greater,

resulting in a more rapid development and termination of the disease and such general widespread effects as increasing torpor and physical degradation, headache, general tremors and convulsions, ataxia and terminal mania. In such cases trypanosomes have been found not only in the capillaries of the brain, but in the brain substance itself (cerebral trypanosomiasis), quite analogous in this respect and in the pathologico-histological changes produced to paresis or infection of the brain substance and perivascular spaces with *Sp. pallida*. I have found similar changes in the brains of some rabbits dying of *Tr. equiperdum* infection and both rats and rabbits are apt to die with the tremors and convulsions characteristic of the terminal stage of trypanosomiasis in human beings. In the early stages of African trypanosomiasis the parasites are found in the blood and lymphatic glands more frequently and readily than in the later stages; consequently during these early months treatment is much more effective than in the later stages when widespread and chronic tissue lesions have developed. These tissue changes are principally in the lymphatic tissues throughout the body, in the meninges and possibly in the muscles (myositis with cysts similar to those produced by *Tr. cruzi* in Chaga's disease). As first shown by Mott, practically every case shows congestion of the meninges with extensive meningo-encephalitis and preivascular round-cell infiltrations throughout the meninges, brain and cord with secondary degenerative changes of the nerve-cells analagous to the histological changes in syphilis (especially paresis). The cerebrospinal fluid is increased in quantity, shows an increase of cells (principally lymphocytes), an increase of protein and sometimes the presence of the trypanosomes (first described by Castellani in 1902). Whether or not changes occur in the sugar-content as in syphilis, I cannot state; neither have I been able to find data upon the complement-fixation and colloidal-gold reactions with the spinal fluid in this disease. The presence of trypanosomes in the spinal fluid occurs so frequently that routine examination of this fluid constitutes an aid in diagnosis. Furthermore, from the standpoint of chemotherapy, the indications are to select a trypanocidal compound possessing the properties of penetration into the cerebrospinal fluid following intravenous injection, and in this connection may be mentioned the recent work of Voegtlin, Smith, Dyer and Thompson,[2] who found in rabbits that sulpharsphenamin, tryparsamid and 3-amino-4-oxyphenyl arsenic acid were remedies of superior penetrative power.

All experimental and clinical evidence shows that from the standpoint of chemotherapy, best results are observed when treatment is given during the early stages of the infection when the parasites are in the blood and lymphatic system and before fixed tissue changes have occurred. The same is true of syphilis, only the necessity for early diagnosis, prompt and *vigorous* treatment are still more important in trypanosomiasis because this disease is more acute and runs its course more rapidly. In the chronic stages of human trypanosomiasis fibrosis of the infected tissues, and especially of the lymph-glands where the trypanosomes may rest, likewise adds difficulties in treatment and requires intermittent treatment over long periods of time as in the treatment of chronic syphilis.

Fortunately trypanosomiasis does not appear to be transmitted to offspring as frequently as in syphilis. According to Greggio, human trypanosomiasis is not, as a rule, transmitted, although the abortion rate is increased from the normal 7 per cent. in the Congo natives to 31.7 per cent., and the infant mortality for 29 to 50 per cent. Among the lower animals I have frequently observed abortion of rats, guinea-pigs and rabbits, when infected with *Tr. brucei* and *Tr. equiperdum*, but have not at the present time been

able to find trypanosomes in the foetuses. Koch, from observation in Ugunda, thought that human trypanosomiasis may be transmitted by the male during coitus. Dourine (*Tr. equiperdum*) of horses is known to be transmitted in this way, but the evidence in support of transmission of human trypanosomiasis is not conclusive.

Chemotherapy and General Treatment of African Trypanosomiasis (Sleeping Sickness).—Even though the lower animals infected with *Tr. gambiensi* or *Tr. rhodesiense* may be cured by the intravenous injection of a single dose of any one of several trypanocidal compounds, this result is not ordinarily obtained in the treatment of human trypanosomiasis. If human beings could be treated early enough, the chances for such success would be much greater; but unfortunately the infection is usually well established before the natives seek treatment. In syphilis the development of the primary lesion usually excites the majority of even the most careless and ignorant to seek some sort of medical aid, but the local irritation produced by the bite of the infected tsetse fly presents nothing that is characteristic and even blood examinations may be negative in the early stages until the trypanosomes have multiplied considerably and invaded the lymphatic glands. As is true of syphilis, *the earlier treatment is instituted in trypanosomiasis, the better are the chances for success;* but in practice, the difficulties of making an early diagnosis are much greater in trypanosomiasis than in syphilis.

Indeed Ouzillean and Lefrou have recently stated that the treatment of the late or sleeping stage is so unsatisfactory that it resolves itself into preventive or prophylactic treatment only, that is, treatment of the first stage to prevent trypanosomanic invasion of the brain and meninges.

A large number of drugs and principally arsenical compounds, have been administered orally in the treatment of trypanosomiasis. The results have been very poor. Absorption is too irregular, the tolerated doses by this route are too small and the disease progresses too rapidly to justify this kind of treatment if it is possible to employ the intravenous, intramuscular or subcutaneous routes of administration. In the treatment of acute syphilis, the old practice of relying upon the administration of mercury and iodid by mouth has been largely abandoned for the same reasons, but in trypanosomiasis the progress of the infection is ordinarily so much faster, that oral administration is even less efficacious. After the trypanosomes have been apparently destroyed, drugs of the arsenical and antimony group may be given by mouth during the year or preferably two years of "watchful waiting" to determine if cure has been accomplished, just as may be practiced in the treatment of syphilis, but otherwise oral administration has no place in the treatment of trypanosomiasis.

The specific treatment of trypanosomiasis of the human being requires the subcutaneous, intramuscular or intravenous administration of trypanocidal agents, just as is true of the treatment of experimental infections. In practice among the African natives intravenous therapy may be very difficult, but it and intramuscular therapy occupy the first positions of choice. As will be shortly discussed, a form of combined intravenous and subcutaneous therapy is probably best. Drugs have also been injected intraspinally (subthecal) in the treatment of the later stages when trypanosomes are to be found in the cerebrospinal fluid, and under certain conditions it would appear that this route of administration has certain advantages.

Since Lingard introduced arsenious acid, Manson sodium antimony tartrate and Broden and Rodhain tartar emetic in the treatment of trypanosomiasis, a large number of organic and inorganic arsenical and antimony compounds have been introduced. Likewise many other substances have

been employed, but it is the consensus of opinion that arsenical and antimonyl compounds have proven most efficacious.

Treatment with Atoxyl.—Of the arsenical compounds, *atoxyl* has been mostly employed. It has the advantage of being administrable by subcutaneous injection and possessing a fairly high trypanocidal activity. A distinct disadvantage is its affinity for the optic nerve and the tendency for producing toxic amblyopia, and the drug should not be used at all if the eye is involved by the trypanosome infection. Atoxyl is more useful in the treatment of the first stages of trypanosomiasis than in the "sleeping sickness stage" although contrary to current opinion, it may bring the disappearance of typanosomes in the cerebrospinal fluid with a decrease of cells and protein. When administered intravenously atoxyl is also capable of exciting reactions of fever, cutaneous eruptions, etc., somewhat similar to those produced by arsphenamin. Atoxyl, however, is not usually responsible for the epileptiform convulsions of trypanosomiasis; rather these are caused by the trypanosomes. Ouzilleau and Lefrow for example, claim that these effects may be due to the disease rather than to the drug and that in the first stage they do not develop at all if care is taken not to give more than 1.5 gm. of atoxyl in a single dose. In the late or sleeping stage, evidences of neurotropism are more apt to develop, not only with atoxyl, however, but likewise with neoarsphenamin and other arsenical compounds indicating that the organotropism (neurotropism) of arsenical compounds at this time is greater than their parasitropism due to the pathological changes of the brain and meninges.

Recently a French Commission on the treatment of sleeping sickness[3] have reported favorably on the use of atoxyl in doses of from 0.5 gm. to as much as 1.0 gm. for adults interspaced with the intravenous injection of tartar emetic in dose of 0.08 to 0.1 gm. Ouzilleau and Lefrou[4] and Lefrou[5] have found that this mixed treatment with atoxyl and tartar emetic not only influenced the early stages of trypanosomiasis but the late stages as well with a gradual improvement of the spinal fluid after 5 to 6 injections of both medicaments. More recently Blanchard and Laigret[6] have reported that in the first stage of trypanosomianis six subcutaneous injections of atoxyl in dose of 0.02 gm. per kilogram of weight at two week intervals, yielded excellent results and especially with regard to the permanent removal of trypanosomes from the circulating blood. Intravenous injections of tartar emetic between the atoxyl treatments aided the results.

Treatment with Arsacetin, Arsenophenylglycin and Amino-oxyphenyl Arsonate.—Arsacetin and *arsenophenylglycin* were at one time employed, but both have proven too toxic for repeated administration. In effective doses they possess a high degree of neurotropism, or affinity for nerve tissue in general and the optic nerve in particular. Pentavalent arsenical compounds generally possess a higher degree of penetration of the arsenic into nerve tissue, followed by injury, than is the case with the trivalent arsenobenzenes. Blanchard and Lefrou[7] have recently reported good results from the use of *amino-oxy-phenyl arsonate*[189] and as previously stated Voegtlin and his associates found that this substance (the sodium salt of 3-amino-4-oxyphenyl arsonic acid) had superior penetrative power for the spinal fluid in rabbits.

Treatment with Arsphenamin and Neoarsphenamin.—Trivalent compounds of arsenic, as *arsphenamin* and *neoarsphenamin*, would appear to be more efficacious in the treatment of the early stages since they are readily reduced in the tissues to the trypanocidally active oxids. Both of these compounds possess an extremely high trypanocidal activity in experimental *Tr. gambiensi* infections, and arsphenamin is especially indicated in the treatment of the late stages of the human disease because it penetrates the cerebral tissues and reaches the spinal fluid somewhat more readily than neoarsphenamin. The results observed in the treatment of human trypanosomiasis with these compounds, have not by any means, however, been as good as observed in the treatment of syphilis. Derwish[8] has recently reported that of 29 cases treated about 8 years ago with salvarsan and tartar emetic 13 are still in good condition, 3 are in fair condition and 13 have died.

Treatment with Tryparsamid.—Louise Pearce[9] has reported a thorough study of *tryparsamid* in the treatment of both early and late cases of African trypanosomiasis in the Belgian Congo caused by *Tr. gambiensi.* I have already described, in the preceding chapter, the results of treatment with this pentavalent compound in experimental *Tr. gambiensi* infections observed by Dr. Brown and Dr. Pearce. The experimental studies were so favorable that it is hoped the compound will mark an advance in the treatment of human infections. In the first stages of the disease the intravenous injection of single doses varying from 2 to 5 gm. was usually followed by a peripheral sterilization in from 6 to 12 hours which lasted on an average of from three to six weeks although in one case a relapse occurred 17 days after treatment. Intramuscular injections were even more efficacious in that peripheral sterilization followed in the same manner and persisted on the average for seven weeks after treatment. The general effects were likewise prompt and satisfactory.

A number of early cases were also treated with 4 to 7 doses of 2.0 to 5.0 gm. at weekly or fortnightly intervals. The preliminary effects were good both in regards to clinical

improvement and the disappearance of trypanosomes, but nothing can yet be stated regarding the ultimate results.

Equally encouraging results were observed in the treatment of advanced cases by injections of 1.0 to 7.0 gm. at intervals of 3 to 14 days. In these cases it is necessary to take into account not only the invasion of the cerebrospinal tissues by the trypanosomes and the resulting injuries, but also the chronicity of the disease, the tendency for trypanosomal relapses and the debilitated condition of many patients.

Under tryparsamid treatment trypanosomes disappeared from the blood, lymph-glands and cerebrospinal fluid of the majority of cases and the cells of the spinal fluids were decreased by 57 to 98 per cent. in an average of 5 weeks. The general effects were likewise good in most instances, as shown by a return of the pulse and temperature to normal limits, improvement in weight, physical appearance and habits, etc. Weekly doses of 3.0 to 4.0 gm. appeared to yield just as good results as semi-weekly doses of 2.0 gm. Doses of 3.0 gm. or over should not be given oftener than once a week and longer intervals may be just as good and less likely to produce the disturbances of vision that occurred in 9 advanced cases treated by Dr. Pearce. Too frequent doses to patients suffering with very advanced trypanosomiasis is are practically the only conditions in which tryparsamid produced any untoward effects like dimness of vision.

Lefrou and Ouzilleau[10] and Chesterman[11] have recently reported favorable results in the treatment of African trypanosomiasis with tryparsamid. The latter treated 40 selected cases, the usual treatment being the weekly intravenous injection of 3 gm. in 10 c.c. of sterile water. The compound was found to be less toxic than atoxyl and in 24 cases without previous treatment, the primary results were good, the spinal fluids of all being restored to normal. Chesterman states that successful treatment demands maintaining the maximum for at least six to eight weeks and a total of 3 to 4 gm. per week for the average adult is sufficient. Morgan[12] has recently reported the apparent successful treatment of a case after relapse following the administration of three injections of atoxyl and ten injections of "Bayer 205."

Treatment with Sulpharsphenamin.—In the treatment of the advanced cases of trypanosomiasis, the indications are to employ trypanocidal agents capable of penetration into the cerebrospinal fluid, inasmuch as the cerebral lesions are most severe and destructive. Recently an experimental study by Voegtlin, Dyer and Thompson[13] employing rabbits infected by the injection of *Tr. equiperdum* into the cranial subarachanoid space, showed that sulpharsphenamin, tryparsamid and 3-amino-4-oxyphenyl arsonic acid were remedies of superior penetrative power. Judged upon the basis of the power of the drugs injected intravenously reaching the subarachanoid space of rabbits and destroying trypanosomes, the effectiveness of the various compounds was in the following order: tryparsamid, sulpharsphenamin, 3-amino-4-oxy-phenyl arsonic acid, arsacetin, atoxyl, neoarsphenamin, arsphenamin, silver arsphenamin and "arsenoxid." So far I have found no reports upon its use in the treatment of African trypanosomiasis, but the results of animal tests certainly justify its trial.

Treatment with Tartar Emetic and Other Antimony Compounds.—Next to the arsenicals, compounds of antimony and especially trivalent compounds, have been firmly established in the treatment of trypanosomiasis. *Tartar emetic* is mostly employed but must be injected very carefully and intravenously, as the least amount in the subcutaneous tissues or muscles produces a very painful local reaction. Likewise it must be well diluted to reduce the chances of unpleasant and even dangerous reactions of vertigo, cough, syncope, unconsciousness, etc. Usually the dose is 0.1 gm. dissolved in not less than 100 c.c. of sterile saline solution or, better, 5 to 10 c.c. of a sterile 1 per cent. solution injected slowly and carefully.

Various new antimonyl compounds have been advocated. Of these *sodium antimony thioglycollate* described by Rountree and Abel[14] has yielded excellent results in experimental infections. The cost is low, it apparently does not readily produce antimony fastness or resistance of trypanosomes and it is readily administered by intravenous or intramuscular injection of 5 to 10 c.c. of a 1 per cent. sterile solution. *A special advantage consists of the fact that these amounts may be injected intramuscularly without producing local irritation;* this renders available, therefore, an antimonyl preparation for the treatment of children or under conditions generally in which intravenous therapy cannot be applied.

Among other antimonyl preparations may be mentioned the *sodium salt of p-amino-phenyl-stibinic acid* produced by Breinl and Nierenstein,[15] *anilin antimonyl tartrate* introduced by Laveran[16] and the *sodium salt of acetyl-p-aminophenyl stibinic acid* ("stibenyl") employed by Manson-Bahr.[17] This compound contains 34.3 per cent. antimony and is tolerated by human beings in doses of 0.6 gm. One case of trypanosomiasis was greatly improved by repeated injections with a total administration of 4.5 gm. The compound is regarded as more active than tartar emetic in the treatment of *Tr. rhodesiense* infections which are well known to be more difficult to treat than *Tr. gambiensi* infections.

Recently Van den Branden and VanHoff have reported the use of the *tartro bismuthate of potassium and sodium* ("luatol"), but as mentioned in the preceding chapter this substance has practically no effect in experimental trypanosomiasis and I doubt if it will prove of value in the treatment of African trypanosomiasis.

Treatment with "Bayer 205."—At the present time a new compound prepared by the Bayer Company and designated as "205" is being tried in the treatment of African trypanosomiasis and the successful treatment of quite a number of cases has been recorded. As stated in the preceding chapter its composition is secret. Kleine and Fisher,[18] Stephens and Yorke[19] and Low and Manson-Bahr[20] have recently reported favorably upon the use of this compound in the treatment of African trypanosomiasis. The latter have treated 8 cases of *Tr. gambiensi* infections in Europeans with good results in 7 cases; one case died of cerebral trypanosomiasis. One case of *Tr. rhodesiense* infection was greatly improved but not cured. They advise the intravenous injection of 1.0 gm. dissolved in 10 c.c. of water as a dose once per week for ten weeks, although *therapia magna sterilisans* may be attempted in early cases by an injection on each of three days in succession. The compound, however, may produce nephritis with albumin and casts in the urine and should be used cautiously until more is known of its composition and toxicity.

Treatment of Early Stages of African Trypanosomiasis Caused by Tr. Gambiensi.—With this general review of the various medicaments proposed for the treatment of trypanosomiasis of human beings, I may now briefly summarize plans for the treatment of the various stages of the disease. My suggestions however, are based entirely upon the results recorded in literature and extensive animal experimentation rather than upon personal experience with the disease in Africa. In the early stages, treatment should extend over a period of at least six months with an additional period of observation of at least one to two years. In the following method the doses of the different medicaments are those suitable for adults of both sexes; children should be given proportionate amounts according to weight rather than according to age.

(1) During the first year arsphenamin, in alkalinized solution, in dose of 0.6 gm. or neoarsphenamin in dose of 0.9 gm. by intravenous injection may be given once a week for 12 to 15 injections. If intravenous injections are not possible or convenient the intramuscular injection of tryparsamid in dose of 2.0 gm. dissolved in 10 to 20 c.c. of water, or subcutaneous injections of atoxyl in dose of 0.5 gm. dissolved in 5 c.c. of water, may be given. Intramuscular injections of sulpharsphenamin or "Bayer 205" may be administered instead.

(2) This course may be followed by a rest without specific medication of one month to be followed by:

(3) Tartar emetic intravenously in dose of 5 to 10 c.c. of a sterile 1 per cent. solution every other week for 12 injections (6 months) or sodium antimonyl thioglycollate in the same dose by intravenous or intramuscular injection. Tryparsamid may be given in dose of 2 gm. in 10 c.c. of sterile water intraamuscularly at the same time each alternate week for 12 injections covering a period of 6 months; or atoxyl may be administered instead in dose of 0.5 gm. in 5 c.c. of water by subcutaneous injection every other week for 12 injections.

(4) This completes the first year of treatment at the end of which time the patient should be given a rest of a month or two under observation and subjected to a thorough examination for trypanosomes as follows: (*a*) Repeated examinations of the blood including, if possible, animal inoculation tests conducted by injecting citrated or defibrinated blood intraperitoneally into mice (dose 1 c.c.) or white rats (dose 2 to 3 c.c.). (*b*) Examination of blood for auto-agglutination. (*c*) A thorough examination of the cerebrospinal fluid for cells, protein and trypanosomes (microscopical examination of centrifuged fluid and injection of fluid or sediment into mice or rate in case of negative direct examination). (*d*) If the glands are enlarged, puncture and examination for trypanosomes.

(5) If evidences of infection are still present, the above courses should be repeated, at least in part. A careful watch should be made for relapses throughout the second year and treatment given if relapse occurs.

(6) During the second year, while the patient is under clinical and laboratory observation, it may be well to give some treatment even though apparently free of infection, like atoxyl in dose of 0.5 gm. subcutaneously or tryparsamid in dose of 2.0 gm. intramuscularly twice a month. Medication by oral administration hardly appears worth while, although hexamethylenamin (urotropin) in dose of 0.25 gm. (4 grs.) three times a day may be of some advantage in preventing invasion of the spinal fluid.

Treatment of Late Stage of Trypanosomiasis Caused by Tr. Gambiensi.— Treatment of the late stage of African trypanosomiasis with cerebral symptoms of torpor is complicated by the presence of chronic lesions and the poor general condition of the majority of these cases. Various complications must be taken into account and specific treatment administered as indicated for individual cases.

(*a*) Tryparsamid may be given in dose of 2.0 gm. dissolved in 20 c.c. of sterile water intramuscularly once a week for 12 to 15 weeks. Or sulpharsphenamin in dose of 0.4 to 0.6 gm. dissolved in 5 to 10 c.c. of sterile water by subcutaneous injection once a week for 12 to 15 weeks. Atoxyl has not yielded very good results in this stage of the disease.

At the same time a weekly intravenous injection of tartar emetic in dose of 5 to 10 c.c. of a 1 per cent. solution in sterile water or sodium antimonyl thioglycollate intravenously or intramuscularly in the same dose. The arsenic and antimony should not be given at the same time and especially if reactions follow. If intolerance for the antimonyl compound develops or reactions occur it is well to interrupt the injections for a week or two or reduce the dosage, but the rule should be to give the patient as vigorous treatment as conditions permit.

Arsphenamin in dose of 0.6 gm. or neoarsphenamin in dose of 0.9 gm. may be given intravenously once a week instead of tryparsamid or sulpharsphenamin, but the latter two have the advantages of being administrable by intramuscular or subcutaneous injection and possibly furnish arsenic in a form more rapidly penetrating to the cerebrospinal fluid than arsphenamin. Of the two latter compounds, arsphenamin is to be preferred although it is more toxic, more apt to produce reactions and more troublesome to administer.

(*b*) The above course may be lengthened or shortened as indicated by circumstances. Careful examinations should be made of the urine for irritation of the kidneys. After a period of rest of 4 to 6 weeks, the course may require repetition, or treatment for the balance of the year may consist of the intramuscular injection of 3.0 gm. of tryparsamid intramuscularly once every 10 to 14 days or 0.5 gm. atoxyl by intramuscular injection once a week.

(*c*) Indications for repetition of the courses of treatment in the second year are based upon physical examinations of the patient and the examination of blood and cerebrospinal fluid mentioned above.

Relapses frequently occur and during the second year it would appear better not to await the development of these but to administer at least two courses of treatment, each consisting of the intramuscular injection of 2.0 to 3.0 gm. tryparsamid every two weeks, alternating with the intravenous injection of tartar emetic in dose of 5 to 10 c.c. of a 1 per cent. solution every two weeks, for a period of 4 months (8 injections of each) followed by one month of rest. Instead of tartar emetic, sodium antimonyl thioglycollate may be used in the same dosage by intravenous or intramuscular injection.

Intraspinal Treatment of Sleeping Sickness.—Eyre,[21] Trout[22] and Marshal[23] have reported good results in the treatment of sleeping sickness following the Swift-Ellis plan for the treatment of paresis and other forms of syphilis of the brain and spinal cord. These observers have injected 0.9 gm. of neoarsphenamin intravenously and ½ to 1 hour later withdrew 20 to 40 c.c. of blood. After allowing the serum to separate over night, spinal puncture was made, spinal fluid allowed to escape and 10 to 20 c.c. of the serum injected. Trout has also employed galyl, atoxyl, tartar emetic, antimony trioxid and other substances instead of neoarsphenamin.

When trypanosomes are found in the cerebrospinal fluid in this stage of the disease, intraspinal therapy would appear indicated at least in those cases which do not respond to intravenous and intramuscular medication. It would appear worth while, however, to add 0.005 to 0.001 gm. of neoarsphenamin to the serum before injection, the technic being exactly the same as described for the treatment of neuro-syphilis in Chapter LXXVI.

Treatment of African Trypanosomiasis Caused by Tr. rhodesiense.—This form of sleeping sickness is encountered in Nyasaland, Rhodesia, Portugese East Africa and other parts of Africa and represents a particularly virulent type of infection tending to run a more rapid course than *Tr. gambiensi* infections.

Atoxyl and tartar emetic are less efficacious unless treatment is begun early and pushed with vigor.

I do not know the value of arsphenamin, neoarsphenamin, tryparsamid and sodium antimonyl thioglycollate in treatment, but on the basis of animal experiments, I believe that these substances possess curative activity for infections with this particular trypanosome. It would appear, therefore, that treatment should be along the same general lines as described above for *Tr. gambiensi* disease. As stated above, Manson-Bahr has recommended particularly acetyl-p-aminophenyl stibiate ("stibenyl") as more efficacious than tartar emetic; this compound is given intravenously in doses beginning with 0.1 gm. for an adult and gradually increased to 0.6 gm.

General Treatment of Trypanosomiasis.—This consists in maintaining the nutrition and weight of the patient. Individuals who are losing weight do not respond well to specific medication and are particularly likely to develop unpleasant reactions interfering with systematic and thorough treatment. Tincture of nux vomica has been recommended. Infected Europeans in the tropics should be removed if possible to cooler climates. Rest and the systematic use of quinin for any concurrent malarial infection should be insisted upon. Fatigue and everything that might depress, should be carefully avoided.

Duration of Treatment of Trypanosomiasis.—Even in the acute early stages there should be a minimum of treatment covering at least one year. Trypanosomes may disappear from the blood and lymph-glands with less—much less—treatment than advised above, but since relapses so commonly occur it is well to over-treat rather than run the risk of under-treating cases, if conditions permit. Patients should be under observation for an additional year and undergo periodic clinical and laboratory examinations analogous to the periodic use of the Wassermann reaction in the treatment of syphilis. The cerebrospinal fluid should be examined at least once or twice and treatment continued until it is restored to normal.

The question of complete cure when treatment is begun in the late stages, is doubtful and probably occurs only in exceptional cases. These cases should be kept under supervision for years and undergo periodic courses of treatment.

Re-infection in Trypanosomiasis.—It is highly probable that the immunity following the cure of African trypanosomiasis is of brief duration and that susceptibility to re-infection exists analogous to re-infection in syphilis when complete cure of the previous disease has been effected. I have not been able to find accurate data upon this point in reference to human beings, but I know that the lower animals can be re-infected with the same strains of trypanosomes about one or two months after the previous infection has been eradicated by specific medication even when, as in rabbits and guinea-pigs, the infection has persisted for 2½ to 7 months. It is not improbable that relapses in human subjects may indeed be true re-infections, since the chances for re-infection by tse-tse flies is so likely in the infested districts of Africa.

Whether or not a case of human trypanosomiasis is immune to super-infection with *Tr. gambiensi* or *Tr. rhodesiense*, as long as he is infected with one of these parasites and uncured, in a manner analogous to the almost complete resistance of the uncured syphilitic to super-infection with *Sp. pallida* after the primary stage of syphilis, I cannot state. On the basis of animal experiments I believe, however, that the immunity developed during treatment is sufficient to protect against super-infection with either *Tr. gambiensi* or *Tr. rhodesiense*. This immunity, however, probably disappears in about one or two months after cessation of treatment with arsenic, antimony or a mixture of these.

Treatment of American Trypanosomiasis (Chagas' Disease).—Unfortunately, there has been very little experimental work done on the treatment of this disease with the more recently discovered arsenical and antimony compounds. Manson-Bahr states "we know of no specific remedy. Arsenicals and antimony have failed in experimental animals. Treatment, therefore, must be on general lines."

As previously stated, the etiological agent is *Tr. cruzi*, also known as *Schizotrypanum cruzi*. The disease occurs in Brazil and Venezuela; possibly also in Peru.

Chagas[24] recognizes acute and chronic types. Children are mostly infected and the parasite produces lesions and symptoms resembling cretinism. Introduced by the bite of infected bugs, the trypanosome multiplies not in the blood, but in the cells of various organs, including the striped muscle, especially of the heart, vertebral muscles, in bone marrow, and other organs and tissues. The parasites then find their way into the blood concurrently with an attack of fever, but usually in small numbers requiring prolonged search. It may be necessary to centrifuge 10 c.c. of citrated blood to find them in smears of the sediment or to inoculate guinea-pigs with 2 to 5 c.c. intraperitoneally, the trypanosomes being subsequently found in the blood, or the developmental forms in the muscles.

Whether or not the trypanosome is susceptible to destruction in human subjects by arsphenamin, neoarsphenamin, tryparsamid or sodium antimonyl thioglycollate cannot be stated; but until suitable animal experiments have been conducted, it would appear worth while to give these substances a trial and especially tryparsamid, sulpharsphenamin and sodium antimonyl thioglycollate which may be administered by subcutaneous or intramuscular injection, since intravenous medication may not be possible in children. The dose of tryparsamid may be 0.050 gm. per kilo (approximately 2 pounds) dissolved in 5 c.c. of sterile water; sulpharsphenamin in dose of 0.005 gm. per kilo dissolved in 2 to 5 c.c. of sterile water and sodium antimonyl thioglycollate in dose of 2 to 5 c.c. of a sterile 1 per cent. solution. Repeated injections are probably required at intervals of 5 to 10 days after the plan described above for the treatment of African trypanosomiasis.

Treatment of Trypanosomiasis of the Lower Animals.—The treatment of trypanosomiasis of the lower animals is not usually undertaken since it is cheaper to destroy the infected animals. In the United States only one trypanosome disease has so far been described, namely, *dourine* or *Tr. equiperdum* infection of the horses of the northwest.

The lesions and symptoms of trypanosomiasis of the lower animals vary with the different parasites. In all, however, the infection is likely to be chronic with infection of the tissues and irregular infection of the blood. In dourine, the tissues of the genital organs are especially involved and diagnosis is aided by the examination of the edema fluid and blood for trypanosomes and by the complement-fixation test.

Practically all that has been written on immunity in human trypanosomiasis and its relation to chemotherapy is applicable to trypanosome infections of the lower animals. Treatment is likewise similar to that described for African trypanosomiasis, except, of course, that the doses of the various medicaments are larger. These doses may be calculated on the basis of kilogram of body weight (approximately two pounds) as follows:

(*a*) *Arsphenamin* in alkalinized solution by intravenous injection in dose of 0.010 gm. per kilo. The dose for a 1600-pound horse would be, therefore, about 5 to 8 gm. dissolved in 500 to 1000 c.c. of water and alkalinized.

(*b*) *Neoarsphenamin,* in dose of 0.015 gm. per kilo dissolved in sterile water. The dose for a 1600-pound horse would be, therefore, about 10 to 12 gm. dissolved in 50 to 100 c.c. of water. Pommrich[25] records the cure of case of dourine in a horse following one dose of neoarsphenamin.

Owing to the cost of these compounds, their administration and especially repeated administration, may be prohibitive. However, biological laboratories preparing these substances usually have on hand batches that are a little too toxic to meet the requirements of safety for the treatment of human beings and yet may prove quite acceptable for the treatment of the lower animals and obtainable at a much reduced price. For example, arsphenamin for administration to human subjects must be tolerated by rats in a dose of 0.120 gm. per kilo of weight by intravenous injection, but compounds tolerated in but 0.050 gm. per kilo would still be satisfactory for the treatment of horses since the maximum amount advised above is at least five or more times less than this dose per kilo of weight. Neoarsphenamin is even safer. For the treatment of human beings it must be tolerated by rats in dose of 0.240 gm. per kilo by intravenous injection, but for horses compounds having a maximum tolerated dose of but 0.150 gm. per kilo are safe, inasmuch as the dose advised above is at least ten times smaller than this amount per kilo of weight. Curasson[26] has reported success in the treatment of trypanosomiasis of the lower animals in Soudan with "galyl" (phospharsphenamin), but since both arsphenamin and neoarsphenamin possess a higher degree of trypanocidal activity it would appear that either of these is to be preferred to galyl.

(*c*) *Tryparsamid* in dose of about 0.040 gm. per kilo dissolved in sterile water. For a 1600-pound horse this would be 30 gm. dissolved in 150 c.c. of water for intravenous or intramuscular injection. Owing to the cheapness of this compound, and the efficacy of intramuscular injections it would appear possible to use it on a large scale.

(*d*) *Atoxyl* in dose of about 0.010 gm. per kilo. For a horse weighing 1600 pounds this would be about 8 gms. dissolved in 80 c.c. of water for intravenous, intramuscular or subcutaneous injection. The cheapness and ease

of administration of this substance also permits it to be used on a large scale in the treatment of selected animals of special value.

Possibly atoxyl has been used more frequently than any other arsenical compound in the treatment of dourine, surra, nagana disease, debab, etc., especially of horses. As a general rule, tartar emetic has been administered at the same time.

Horses sometimes develop well-marked degrees of intolerance for both drugs, and due caution must be exercised.

(*e*) *Tartar emetic* in dose of about 0.010 gm. per kilo. For a 1600-pound horse this would be approximately 1000 c.c. of a 1-per cent. solution in water by intravenous injection. As previously stated, tartar emetic requires a dilution of about 1 per cent. and intravenous injection. Subcutaneous and intramuscular injections produce severe local reactions. Sergent and Donatein[27] have recently reported upon the successful treatment with tartar emetic of trypanosomiasis of dromedaries ("debab"); Sergent and Foley[28] in a comparative study of "afridol" (a benzidin dye), trypan-blue and tartar emetic in experimental trypanosomiasis of dromedaries, observed best results after a combination therapy of atoxyl and tartar emetic. Van den Branden[29] has used with success tartar emetic, atoxyl and tryparosan in the treatment of surra (*Tr. evansi*) infections of cattle.

(*f*) *Sodium antimonyl thioglycollate* in dose of about 0.02 gm. per kilo. The compound may be given intravenously or *intramuscularly* in a 1 per cent. solution and for a 1600-pound horse the dose would be 150 c.c. of a sterile 1-per cent. solution. The particular advantage of this new compound is the fact that it may be administered intramuscularly without local irritation.

(*g*) At the present time "*Bayer* 205" is being extensively employed in the treatment of trypanosomiasis and favorable reports have been rendered by Baerman,[30] Migone and Osuna[31] and Miessner.[32] For horses the dose may be 2 to 4 gm. in 10 c.c. of saline solution injected intravenously every 8 days.

In the *treatment of dourine, surra, nagana disease, mal de caderas, debab* and other trypanosome diseases of horses, cattle, camels, etc., repeated doses are required, accompanied by blood examinations for parasites very much along the same lines previously outlined for the treatment of African trypanosomiasis of human beings.

PART IV

CHEMOTHERAPY OF SPIROCHAETAL DISEASES OTHER THAN SYPHILIS

CHAPTER XXI

PRINCIPLES OF EXPERIMENTAL SPIROCHAETOSIS IN RELATION TO CHEMOTHERAPY AND THE TECHNIC OF SPIROCHAETICIDAL TESTS

Owing to the world wide distribution and tremendous economic importance of syphilis it is not surprising that the chemotherapy of experimental spirochetic infections has always held the first place of interest and importance. Furthermore, the occurrence of other spirochetic and leptospira diseases among human beings as relapsing fever, frambesia tropica, infectious jaundice, rat-bite fever, Vincent's angina, etc., have added to the importance of chemotherapeutic investigations in spirochetic diseases. Owing to the greater difficulties surrounding chemotherapeutic investigations in experimental syphilis and the longer time required for the evaluation of results of studies with any one compound or group of substances, less work has been done than in the chemotherapy of experimental trypanosomiasis, although, since the discovery of arsphenamin and neoarsphenamin, a very large number of new compounds have been brought forward for the treatment of syphilis. In many instances, however, these new compounds have not been subjected to thorough preliminary studies for toxicity and spirocheticidal activity in the lower animals but rushed too quickly into the treatment of human subjects.

Influence of Technic upon the Evaluation of the Results of Spirocheticidal Tests.—It cannot be too strongly emphasized that the values expressed in the following chapters are to be broadly viewed in their interpretation. It is not possible to place a biological test involving two living things (animal host and test parasite) upon a basis of mathematical accuracy. This is even more difficult in experimental spirochetic than in trypanosome infections because the lower animals display greater variations in natural resistance to infection, immunity develops more quickly, it is more difficult to numerically control the degree of infection and more difficult to find the spirochetes in the tissues of the infected animals. Just as in the chemotherapy of experimental trypanosomiasis, the animal employed, the number of infecting spirochetes inoculated, the interval elasping between the time of infection and the administration of treatment, are factors of importance influencing the results. Furthermore, it is to be borne in mind that *different investigators working with presumably the same substance may secure different results because of variations in the purity and exact chemical constitution of the compound employed respectively by each.*

Practical Value of Chemotherapeutic Studies in Experimental Spirochetosis.—Chemotherapeutic studies in experimental spirochetic infections of the lower animals produced by different organisms have not only greatly aided the advancement of our knowledge of the underlying or fundamental principles of chemotherapy, but have had a more direct bearing upon the treatment of disease of human beings than similar investigations in experi-

mental trypanosomiasis. The treatment of experimental relapsing fever of mice, for example, has completely revolutionized the treatment of relapsing fever of man since one or more administrations of arsphenamin cures the infection in both and was first discovered in experiments employing mice. The same is true of the treatment of experimental yaws or frambesia (*Sp. pertenuis*) infections of rabbits, which resulted in the discovery of the wonderful curative properties of arsphenamin and neoarsphenamin for this disease in both rabbit and man. Likewise the chemotherapy of experimental syphilis of the monkey and more especially of the rabbit, has had a direct and valuable bearing upon the treatment of human syphilis. In addition to these examples may be mentioned the application of knowledge secured in the chemotherapy of experimental spirochetosis to the treatment of rat-bite fever, Vincent's angina, bronchial spirochetosis, etc., of human beings.

Experimental Spirochete Infections Commonly Employed in Chemotherapeutic Investigations.—In Europe *Spirochæta recurrentis* (*Spirochæta obermeieri*), the cause of European relapsing or recurrent fever of human beings, has been mostly employed in experiments employing white mice and rats. *Spirochæta duttoni* and *Spirochæta kochi*, the causes of African relapsing fever, have been less frequently employed. In America *Spirochæta novyi*, the cause of American relapsing fever, has been used to some extent. All investigators have employed infected mice or rats and the four spirochetes produce almost identical symptoms and lesions in these animals, although *Spirochæta novyi* is regarded by Fraenkel,[1] Strong[2] and others as a distinct species, chiefly on account of the immunity phenomena. As a general rule light infections are not fatal and owing to the cyclic remissions, the experimental animals in chemotherapeutic studies must be kept under observation for many weeks (as long as 60 days according to Hata) before the results may be evaluated. It is possible, however, to infect mice so heavily that death occurs in a few days unless the parasites are destroyed by some medicament like arsphenamin or neoarsphenamin.

Spirochæta gallinarum, the cause of relapsing fever in fowls, has been employed by Ehrlich and Hata and apparently is more readily destroyed in experimental fowl infections than the spirochetes of relapsing fever of mammals; unfortunately, however, the rapid development of immunity in this infection with spontaneous recovery, reduces the value of this infection for studies in experimental chemotherapy.

Spirochæta pallida infections of rabbits is now commonly employed for experimental chemotherapeutic investigations in syphilis. The ease with which these animals may be infected and handled in large numbers, the frequency of skin, glandular, osseous and other lesions corresponding to those observed in human syphilis, render these experimental infections very useful.

Application and Utilization of Experimental Spirochetosis in the Development of Chemotherapy.—Comparative tests with various dye and arsenical preparations in the treatment of experimental trypanosomiasis (rat) and spirochetosis (*Sp. gallinarum* and *Sp. obermeieri*) have shown that the spirochetic infections are more readily influenced and cured. Mercurial compounds, which in sublethal amounts are without appreciable effect upon experimental trypanosomiasis in rats, are decidedly more efficacious in the treatment of rabbit syphilis and rats infected with *Sp. novyi* or *Sp. obermeieri*. Apparently these spirochetes are more susceptible to the destructive effects of mercurial compounds than are the various trypanosomes and in chemotherapeutic investigations with mercurial compounds experimental spirochetic infections are to be preferred. Substances without demonstrable

trypanocidal activity *in vivo* may be spirocheticidal; therefore, in chemotherapeutic investigations designed for the preparation of compounds for the treatment of syphilis or other spirochetic infections, the results of tests with trypanosome infections may be misleading and insufficient. On the other hand, compounds exerting trypanocidal effects are very apt to prove spirocheticidal; this is an established fact with arsphenamin, neoarsphenamin, sodium arsphenamin, sulpharsphenamin, etc., as discussed in Chapter XII.

Unfortunately, the low virulence of the spirochetes of relapsing fever for rats and mice, unless an overwhelmingly large infection is induced, the usual and frequent remissions and the tendency for the development of immunity and spontaneous recovery, reduce the value of these experimental infections for chemotherapeutic research. In fowl spirochetosis the rapid development of immunity and spontaneous recovery also interfere with the interpretation of experiments and introduce the error of ascribing curative properties to the agents under study which they do not actually possess.

Probably the treatment of syphilis of rabbits is best adapted for the development of experimental chemotherapy of syphilis. With arsenical compounds preliminary tests may be conducted with trypanosome infections, but some inorganic arsenical compounds may be without demonstrable trypanocidal activity in the maximum amounts that may be given rats and yet demonstrate some degree of spirocheticidal activity in rabbits. As a general rule, testicular infections are produced and the results of treatment evaluated by the rate of disappearance of spirochetes from the lesions, the clinical effects and lastly by inoculation tests for spirochetes in the lymph-glands. Insofar as the rate of disappearance of spirochetes from the testicular lesions is concerned, the results are available within a week after treatment is given, but the final results may require periods of observation as long as four months. For this reason, coupled with the greater expense of using and maintaining the large number of rabbits required for these tests and the lymph-gland control transplantations, rabbit syphilis tests can hardly be used for routine work, but reserved for the final testing of the more promising compounds developed for the treatment of human syphilis.

Much that has been stated in Chapter IX on the principles of experimental trypanosomiasis in relation to chemotherapeutic investigation is applicable to the present subject of spirochetic infections. One meets with similar variations in the virulence of the organisms and the influence of animal passage upon virulence and the results of therapeutic tests. The danger of "drug fastness" is just as important. As a general rule, the results of therapeutic experiments in spirochetic infections are more diffcult of proper interpretation and evaluation because of the relatively low virulence of the organisms for the lower animals and tendency for the development of immunity and spontaneous recovery.

Technic of Spirocheticidal Tests Employing Mice.—For these tests *Sp. recurrentis* (*Sp. obermeieri*) has been generally employed in Europe; the writer has employed *Sp. novyi.*

The strain is propagated in the usual manner by securing blood from a seed animal during a period when spirochetes are present in the blood and injecting fresh animals intraperitoneally. In order to avoid bacterial contamination, I have usually secured blood from the heart of the seed animal as described on page 207. With a sterile 1 c.c. syringe fitted with a gauge No. 22 needle and loaded with 0.5 c.c. of warm saline solution, about 0.1 c.c. of blood is readily aspirated from the heart and 0.2 c.c. of the mixture injected intraperitoneally into several mice. As a general rule, these transmissions are required only twice a month to maintain a strain of moderate virulence.

For conducting chemotherapeutic tests, adult mice of approximately 15 to 20 gm. weight are employed. These may be infected with relatively small numbers of organisms, in

which case the mice survive for several weeks or indefinitely with frequent remissions or they may be infected heavily in which case the majority of animals succumb during the first two weeks of the experiment with organisms almost constantly present in the blood as in trypanosomiasis. The latter method has proven the more useful in my work.

The blood of the seed animal is first examined by placing a drop from the tail on a slide, and examining microscopically. If large numbers of spirochetes are present, the animal is anesthesized and bled into about 5 c.c. of warm 1-per cent. sodium citrate in physiological saline solution, by severing the vessels of the neck and collecting the blood by means of a funnel. A drop of this mixture is then examined microscopically and diluted, if necessary, to show about 50 spirochetes in each field. Animals are now injected intraperitoneally with 0.2 c.c.; the injections are made as rapidly as possible because the citrate-saline solution is toxic and tends to destroy the spirochetes with the production of irregular infections in a series of mice. In every therapeutic test at least 4 infected mice are not treated, but kept for controls. Twenty-four hours later, the majority of mice will show a few organisms in the blood varying from 3 to 5 in each field. The drug is administered at this time either by intravenous or intraperitoneal injection.

Each animal is carefully weighed after fasting for at least 12 hours, and the dose given per gram of weight. Intravenous injections are given in a tail vein, the technic being described in Chapter II.

Daily microscopical examinations are made of the blood from the tail of each animal, including the controls, and the results recorded in the same manner as described on page 204 for the trypanocidal tests. In the untreated controls, the organisms rapidly proliferate in the blood so that by the second day they may reach 50 or more per field (Fig. 14), and on the third day appear in abundant masses. Nearly all untreated animals succumb during the crisis from the 5th to 12th days after inoculation.

FIG. 14.—BLOOD OF A RAT INJECTED WITH SPIROCHAETA RECURRENTIS.
Drawing made from a dark-field illumination just before the administration of arsphenamin.

In lighter infections, a relapse occurs on or about the fourth day, which lasts approximately three days followed by the presence of spirochetes in the blood for two or three days and another relapse. Third and fourth relapses may also occur, the periods of intermission becoming longer and tending to spontaneous cure. Great care must be exercised in making the microscopical examinations, because spirochetes may escape detection. As a general rule, the experiment can be terminated arbitrarily at the end of three weeks, although mice showing no spirochetes at this time are not necessarily sterile but may be in a period of remission of the infection. As shown by Breinl and Kinghorn,[13] inoculation of the blood in this apparent parasite-free period may yield positive results, and for this reason a negative microscopic examination of the blood cannot be accepted as evidence of sterility. Hata[4] has kept mice under observation for as long as 60 days before terminating an experiment and draws particular attention to errors due to individual variation in susceptibility of mice and the influence of acquired immunity. As a final test of cure, Hata sometimes re-inoculates the mice with larger numbers of spirochetes; in animals that had been promptly cured re-infection will occur whereas in uncured animals re-infection does not take place, owing to the acquired immunity engendered by surviving spirochetes even in long periods of remission during which the blood is apparently free of parasites by microscopical administration.

By comparing the results with the untreated controls, it is possible to express the results at any arbitrary period. I always include arsphenamin in each lot of tests, in order to compare new compounds with this substance and to enable an evaluation in terms of the "arsphenamin coefficient" as described in Chapter X.

Technic of Spirocheticidal Tests Employing Rats.—These tests are sometimes unsatisfactory, owing to the fact that rats are capable of rapidly developing an immunity to *Sp. obermeieri* and *Sp. novyi*, which may result in complete recovery soon after infection and lead to error in the interpretation and evaluation of results.

Young rats of about 100 gm. are to be preferred. When inoculated intraperitoneally with 0.5–1.0 c.c. of blood containing 30–50 spirochetes in each microscopic field, the spirochetes appear in the blood within 24 to 40 hours, unless the strain is highly virulent, in which case they may appear as early as eighteen hours after inoculation. As a general rule, the spirochetes remain the blood for about 3 to 4 days, when they gradually disappear. Relapses are rare and completely recovery with resistance to re-infection is the rule.

In my experiments, *Sp. novyi* has been employed, the rats being inoculated intraperitoneally as described and injected with the drug intravenously 24 hours later. In each experiment at least four untreated controls were included. Medicaments are given according to body weight and the tail blood of each animal examined microscopically each day for about four days. Under these conditions, the results are expressed according to the smallest amount of medicament per kilogram of body weight capable of sterilizing the animal 48 hours after treatment (72 hours after infection).

Experimental Syphilis of the Rabbit.—In 1906 Bertarelli[5] succeeded in transmitting *Spirochæta pallida* to rabbits by inoculation of the anterior chamber of the eye with the production of syphilitic keratitis. This discovery showed that these animals were susceptible and opened up a means for the experimental chemotherapy of syphilis. In 1907 Parodi[6] succeeded in inoculating the testicles of rabbits and this procedure is now commonly employed in preference to corneal inoculations. In 1908 Hoffman, Löhe and Mulzer[7] succeeded in producing infection of the skin of the scrotum of rabbits, and Levaditi and Yamanouchi[8] succeeded in inoculating the prepuce. Since then the subject of experimental rabbit syphilis has been extensively studied and especially in America by Brown and Pearce,[9] who have brought this animal infection to a stage of development quite near that of the human disease.

Choice of Organism.—From the standpoint of experimental infections for chemotherapeutic investigations, preference should be given a strain of spirochetes that has been passed from rabbit to rabbit for many generations. In this manner the strain becomes adapted to the tissues of this animal, probably acquires or at least maintains a high degree of virulence and produces uniform lesions so essential for the proper interpretation and evaluation of chemotherapeutic studies. Brown and Pearce, in their extensive and valuable studies over a period of four years, employed two strains of *Spirochæta pallida*, one having been isolated by Zinsser and Hopkins in November, 1913, from a mucous patch (Strain A) and the second by Nichols from the spinal fluid of a case of neurorecidive in June, 1912. My own work has been largely conducted with the latter strain.

Choice of Animals.—Young animals with well-developed testicles and thin scrotums are to be preferred to old animals with redundant, thick and fibrous scrotums and atrophic testicles. The small or medium-sized albino, common gray, brown or Dutch belt rabbits are quite satisfactory for the production of testicular lesions and the general lesions of syphilis. As recently shown by Chesney[9a] young rabbits react to an intratesticular inoculation of the syphilitic virus with a slightly more marked initial lesion than do older animals similarly inoculated, and tend to postpone slightly the appearance of subsequent generalized lesions, which are less severe in character and extent.

Methods for Propagating Strains of Spirochæta Pallida.—Practically the only reliable and serviceable method for propagating *Spirochæta pallida* is from rabbit to rabbit; cultures in artificial media soon lose their virulence. At suitable intervals stock rabbits may be infected by scrotal or testicular inoculation with material from the testicles of syphilitic rabbits, but lymph-gland emulsions are especially to be recommended.

As shown by Brown and Pearce,[10] spirochetes survive in the lymphoid tissues for long periods of time even during latency in which there are no clinical evidences of infection.

For this reason, Pearce and Brown have advocated propagation of the strains employed for chemotherapeutic work by injecting fresh animals with emulsions of the ground up glands of seed syphilitic rabbits. Under this plan it is merely necessary to keep a sufficient number of infected animals to guard against loss of the strain by their death. Serial transfers may be dispensed with.

When it is desired to recover the organism, a popliteal node may be excised under anesthesia and with aseptic precautions, minced, and ground in a mortar; an emulsion is then prepared by the addition of about 1.5 c.c. of sterile normal saline solution with further grinding. It is not necessary or advisable to use foreign substances, as sand, to aid in the grinding of the material. The resulting fluid is simply aspirated into a small syringe fitted with gauge 22 needle and about 0.5 c.c. injected into a testicle of one or more normal rabbits. In order to allow ample time for the development of a testicular infection, the inoculation should be made 6 to 8 weeks before the organism is needed for the infection of a larger number of animals for chemotherapeutic or other purposes.

Choice of Lesion.—As previously stated inoculation of the cornea is no longer employed. For purposes of chemotherapeutic investigations testicular lesions are more satisfactory and the percentage of "takes" with a good laboratory strain is very high; but they are on the whole of less value as objects of clinical study than skin (scrotal) inoculations, because a large part of the process takes place in parts hidden from direct observation and the infection is of a less stable character. Skin inoculations, on the other hand, are more akin to the mode of infection in the human being and the lesions are more analogous to the primary lesions of man. The lesions are likewise more accessible to observation and the results of chemotherapy readily observed.

However, the testicular lesions are just as easily examined for spirochetes by dark-field examination and the results of treatment may be evaluated with comparative ease by noting the influence upon the size of the lesion and disappearance of the organisms. Chesney has tried intradermal inoculations but observed that generalized syphilis is less prone to develop than in the case of intratesticular inoculations. However, even though the primary reaction to intradermal inoculation may be slight or absent, general invasion of the body with spirochetes may take place, as evidenced by positive lymph gland transfers, even though no generalized lesions may be observable. Chesney and Kemp[10a] have also shown that rabbits can be successfully infected with syphilis by the inoculation of surface wounds with virulent strains of *spirochæta pallida.*

Technic and Course of Testicular Syphilis of the Rabbit.—A seed animal should be chosen presenting a well-developed testicular lesion and showing numerous actively motile spirochetes by dark-field examination. *But care must be exercised against using testicular lesions at the time of regression and showing large numbers of agglutinated immobile spirochetes. The infectivity of these is greatly reduced and approximately* 10 *times more are required for successful inoculation.* In this connection it is interesting to record in passing that Miss Rule and I have kept excised syphilitic testicles from rabbits in a refrigerator at about 12°C. for as long as two weeks, finding that the spirochetes were still slightly motile at end of this time and capable of infecting rabbits upon testicular inoculation. I mention the matter here to indicate that the organisms may survive for long periods of time under such conditions and that undue haste in transplanting is not required.

The material or a portion of it is placed in a sterile mortar and finely minced with sterile scissors, after which enough sterile saline solution is added to moisten the entire mass. The material is then rubbed to a paste, more salt solution being added so as to give about two or three spirochetes in each microscopic field by dark-field examination. Usually two to five volumes of salt solution are required to one of tissue. The fluid emulsion is then aspirated into a small sterile Record or Luer syringe fitted with a sharp, smooth guage 22 needle about $\frac{5}{8}$ inch in length. The scrotum of the animal to be inoculated is sponged with 1-per cent. tincture of iodin and 0.2 to 0.5 c.c. of the emulsion injected into the center of each testicle (Fig. 15). As shown by Chesney and Kemp[10b] the size of the dose of the infecting material exerts an appreciable effect upon the duration of the incubation period in experimental syphilis of the rabbit. Other things being equal, the larger the dose the shorter is the incubation period. However,

the size of the inoculum was not found to exercise any marked effect upon the course of the disease as a whole; rabbits inoculated with minimal amounts may run a malignant course.

In from 7 to 10 days, spirochetes may be found in the testicles by dark-field illumination; likewise histological changes are usually present, although

FIG. 15.—TECHNIC OF TESTICULAR INOCULATION OF THE RABBIT.

the testicle may appear normal and show no gross signs of infection. In from 3 to 4 weeks after inoculation, however, clinical signs of infection are usually

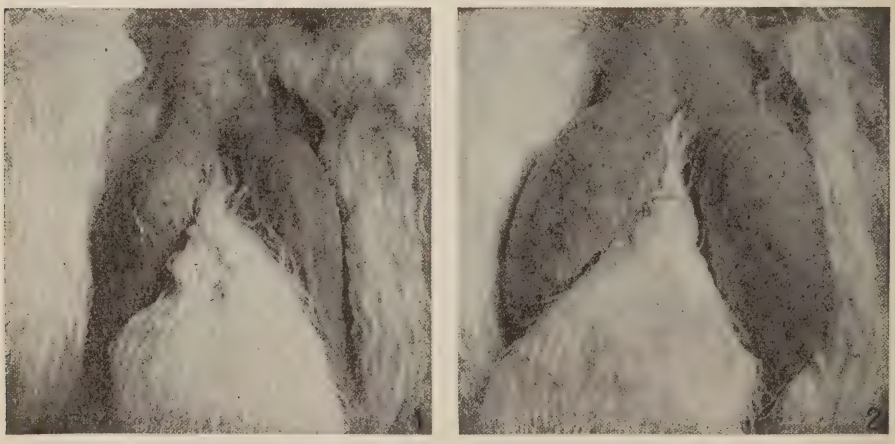

FIG. 16.—ACUTE SYPHILITIC ORCHITIS IN A RABBIT.
Normal testicles on the left; well advanced, acute syphilitic orchitis with beginning congestion and edema of the scrotum on the right. (Brown and Pearce.)

apparent, unless the inoculation has been from old, inactive, or regressing lesions in which case the period of incubation is of longer duration.

As a general rule, the testicle first presents either a diffuse swelling with increased tension or a small circumscribed focus of induration situated at the point of inoculation. The testicle may now become acutely swollen with reddened skin and considerable edema (Fig. 16), terminating in a crisis followed by a slight secondary cycle of proliferative reaction. This type of reaction is especially likely to develop when rabbits are inoculated at short intervals from acute progressive lesions. Dark-field examination shows that the spirochetes increase with the orchitis, so that by the time the lesions have reached their height, actively motile organisms are present in large numbers. At the crisis, the spirochetes suddenly lose their motility, collect in conglomerate masses, rapidly diminish in numbers and show loss of motility and evidences of degeneration. After passing through a crisis of this kind, they may again increase in numbers and motility presaging a renewed activity on the part of the orchitis, these parallel cyclic changes continuing throughout the existence of the local lesion.

On the other hand, enlargement of the testicle may take place more slowly and steadily for 2 or 3 weeks by which time the organ presents a large, smooth or slightly nodular lesion of extreme hardness. Instead of a pronounced crisis, this lesion regresses more slowly, the testicle becoming soft and gradually reduced in size leaving a diffuse residual induration. This is followed by cycles of activity and remissions for a considerable period of time. This type of lesion is especially apt to develop when inoculations are made at long intervals or from chronic indurative lesions. Dark-field examination reveals spirochetes, but not usually in as large numbers as met with in the acute exudative lesions.

In addition to these two typical forms of orchitis, one sometimes sees lesions partaking of the features of both, what may be designated as subacute orchitis in which the features of acute exudation and infiltration are associated with proliferative changes in the tissue cells. In practically all instances, the infection ultimately involves the entire organ—a panorchitis—with lesions in the parenchyma, tunics, epididymis and cord, and in many instances the skin as well.

During the latter part of the orchitis the spirochetes become fewer and more difficult to find. Sometimes spirochetes are found in one portion of the testicle and not in another, but as a general rule the active areas and quiescent lesions, not regressing, show large numbers of motile spirochetes.

The duration of these local lesions is quite variable, being inversely proportional to their intensity. In some animals the entire reaction is one intense cycle of acute reaction terminating in 4 to 6 weeks after inoculation. In others, the infection continues in successive cycles, but the period of active infection rarely lasts longer than 2 to 4 months. Inactive or latent lesions and residual lesions in the epididymis, skin, and tunics sometimes persist for from 4 to 12 months.

Technic and Course of Scrotal Syphilis (Chancres) of the Rabbit.—Young animals should be chosen in which the scrotum is thin and as free from hair as possible. Large and old rabbits with more or less ample or redundant scrotums are poor subjects for the production of scrotal chancres. The best animals are those just approaching full maturity. Belgian and Flemish giants give poor results, while the small albinos, grays, browns and Dutch belts are more satisfactory.

The technic of inoculation commonly employed is essentially the same as that described by Tomasczewski,[11] which consists in the implantation of a small piece of infected tissue in a pouch prepared for it in the scrotum.

The tissue is generally secured from the testicle of a seed animal as described above, being removed with as little contamination as possible and cut into pieces measuring from 2 to 5 mm. in diameter. Due to unequal distribution of spirochetes in infected tissues as well as to inequalities in virulence, inoculations by this method may not be uniform. But, according to Brown and Pearce, these difficulties may be overcome by the observance of certain precautions: First, the use of infected tissues at a relatively early stage of the infection or only at a period when the infection is actively progressing; second, the use of only such portions of a lesion as are actively growing at the time; and third, as a means of insuring an adequate dose of organisms when any doubt exists, the use of pieces of tissue as large as can conveniently be used without causing necrosis and sloughing of the surrounding tissues.

The animal to be inoculated is fastened to an operating board or held by an assistant and the scrotum sponged with 1-per cent. tincture of iodin, stronger antiseptics sometimes destroying the spirochetes and irritating the skin. Anesthesia is not required. The superficial layers of the skin are snipped with scissors and a small pocket made with forceps in the subcutaneous tissue as superficially as possible, in which a fragment of infected tissue is introduced for the distance of at least half an inch. Or the inoculation may be made with a trocar needle of 8 to 9 guage. Brown and Pearce have also produced superficial lesions by injecting intracutaneously or subcutaneously 0.1 to 0.2 c.c. of a saline suspension of testicular material containing at least 5 to 10 spirochetes in each dark-field and prepared as described above. This method has the advantage of causing less trauma but sometimes results in producing a more diffuse lesion than desired.

With the *method of tissue transplantation* the period of incubation varies from 10 days to 2 weeks, but may be prolonged for months in cases of inoculation of few organisms or of organisms of low vitality. The early reaction is a combination of irritation by the inoculated tissue, wound healing and the specific reaction. The traumatic reaction usually subsides in 2 to 3 days and healing of the incision is generally complete within 7 to 10 days, although sometimes an ulcer develops over the transplanted tissue and especially if bacterial infection has occurred.

Edema and congestion of the scrotum now develops with necrosis of the skin over the transplants and the formation of hard dry crusts which show a line of demarcation at their periphery. The edema and congestion gradually involve the scrotum of both testicles due to the inherent tendency of *pallida* infections to spread beyond the local confines of the initial lesion; multiple chancres may develop.

With the *method of injection of spirochete emulsion*, the incubation period may be as short as 1 week or delayed for 4 weeks; usually lesions developed within 10 days to 2 weeks after inoculation.

Usually the first sign of the chancre is a small, soft, gelatinous swelling of a rose-pink color situated in the papillary and reticular layers of the skin and frequently associated with a rich vascular network or the lesion may first appear as a more superficial minute translucent nodule or as an opaque, white nodule of extreme hardness in the depths of the skin and usually connected with the outer surface of the tunica vaginalis. From these initial points the lesions develop into elevated masses with necrotic centers covered with dry crusts and gradually involving the whole scrotum, the cause and development of the lesions varying somewhat according to the character and location of the initial lesion.

The resulting chancres from either method of inoculation are subject to wide variation in extension and appearance. Usually they are nodular and

of irregular spherical form, with small sharply circumscribed areas of superficial ulceration and accompanied by extreme induration. Or they may appear as lenticular and discord lesions of a more flattened character, with more widespread necrosis and a lesser degree of induration. Sometimes the lesions are very atypical and diffuse with marked fibrosis of the scrotum, running a prolonged course and sometimes with the development of small areas of necrosis.

The subsequent course of these chancres is very irregular. As a rule, a period of growth lasts for 2 to 3 weeks followed by an interval of inactivity. As long as the lesion is active or quiescent it retains its appearance unaltered, but as soon as regression sets in the skin becomes lax and wrinkled, the induration less and the lesion smaller in size. As a general rule, three or four cycles of activity and regression will occur, but not infrequently is limited to a single cycle; the duration of the scrotal lesion may vary, therefore, from 1 to 12 months or longer. In the majority of instances the infection terminates by degrees, healing taking place with the production of a scar and requiring about 4 to 6 weeks for completion.

Spirochetes are to be found in the secretion from these lesions, but their number is subject to wide fluctuation and bears no constant relation to the size of the lesion since large numbers may be found in relatively small and insignificant chancres. As is true of testicular lesions, most spirochetes are to be found in the developing progressive lesions and especially at the periphery of chancres of cellular or mucoid character. In regressing healing and fibrous lesions they are apt to be scarce and one may fail to find them in dark-field examinations. These facts should be kept in mind in the course of chemotherapeutic investigations in order to avoid the error of ascribing spirocheticidal properties to a drug under study when the failure to find spirochetes may be due to the character of the lesion.

Furthermore, the size of the chancre is no index to the degree of general infection that may follow; some of the most severe generalized infections may follow the most insignificant chancres and indeed, large chancres tend to inhibit the development of other focal infections, as discussed later in more detail.

Generalized Syphilis of the Rabbit.—In addition to the tendency for local dissemination of syphilis in the scrotum and testicles of rabbits, described in the preceding sections, it is now well established that a more widespread distribution may occur in which distant tissues and organs may be involved. In 1909 Uhlenhuth and Mulzur[12] reported metastatic infection from one testicle to the other testicle and scrotum and a second case of metastasis to an uninoculated testicle after removal of the infected testicle. At about the same time Ossola[13] and Truffi [14] demonstrated virulent spirochetes in the inguinal lymph-glands of infected rabbits and since then metastases of this kind have been frequently noted and especially studied by Brown and Pearce, the latter investigators showing that the rabbit may develop practically all the lesions of syphilis known to occur in syphilitic human subjects like syphilitic adenitis, cutaneous and muco-cutaneous lesions, lesions of the eyes, bones, cartilage, tendons, etc. For a description of these and the literature upon the subject, I refer the reader to the excellent series of papers by Brown and Pearce.[15] Doubtless many of the lesions developed in rabbits have hitherto been disregarded or overlooked and ascribed to the effects of trauma or other infections until shown to be generalized metastatic lesions of syphilis by their extensive and thorough studies.

As shown by Brown and Pearce, when rabbits are inoculated in both testicles generalized lesions develop in about 20 per cent. of animals; when

inoculated in one testicle generalized lesions develop in about 50 per cent. of animals. This difference is ascribed to the production of immunity principles by the tissues of the testicles, tending to inhibit the dissemination of the spirochetes; the immunity is less when one testicle is infected than when both organs are inoculated.

Furthermore, if rabbits are castrated soon after inoculation generalized syphilis is especially apt to occur. For example, as shown by Brown and Pearce, if rabbits are inoculated in one or both testicles and castrated 2 to 14 days later, generalized syphilis occurs in practically all animals. Brown and Pearce have also shown that, if the testicular lesions are suppressed by the injection of a therapeutic agent (6 mg. per kilo of arsenophenylglycyl dichloro-m-aminophenol 14 days after testicular inoculation in their experiments), generalized syphilis may be produced in the majority of animals. These experiments show that in the rabbit the local lesion tends to inhibit the development of lesions elsewhere and that the reduction or supression of the local reaction by the use of any means that does not remove or destroy all of the spirochetes, removes this control and tends to increase the occurrence of generalized lesions and the severity of the infection.

For the production of generalized syphilis for purposes of chemotherapeutic investigations, one may inoculate rabbits in one or both testicles and castrate about 7 days later.

Of further interest in this connection are the observations of Brown and Pearce[16] that, by various experimental procedures, it was possible to produce different types of generalized infection with a definite sequence of tissue involvement or of tissue reactions, which made it possible to produce infection or to confer protection on a given group of tissues according to the nature of the means employed. These investigators have concluded that a wide variation in the clinical types of syphilis in the rabbit might be traceable to this group of experimental causes. This, of course, does not eliminate the possibility that there are different strains of *Spirochæta pallida* producing certain lesions by selective tissue tropism as first suggested by Noguchi[17] and later studied by Nichols,[18] Reasoner,[19] Levaditi and Marie,[20] Marie, Levaditi and Banu[21] and others discussed at length in Chapter XXXVI, but the experiments of Brown and Pearce demonstrate that great care should be exercised in drawing conclusions in this subject, since the distribution of spirochetes is apparently influenced to some extent at least by experimental factors aside from the possibility of some strains being endowed with the property of localizing specifically in certain tissues.

Criteria of Cure of Rabbit Syphilis.—In view of the fact that spirochetes may be found in the popliteal, inguinal and other lymphatic glands of syphilitic rabbits many weeks and months after inoculation and apparent recovery, it is doubtful if this animal is able to bring about complete cure unaided by antispirocheticidal drugs as is also apparently true of human beings. As stated in the preceding pages, syphilis in the rabbit tends to pursue a cyclic course of exacerbation and regression of lesions and the periods of latency may be so prolonged and the animal to all appearances so completely recovered and well, that one may readily enough fall into the error of regarding the animal as cured. If, however, the lymph glands are removed, ground up and the emulsion injected into the testicles of normal rabbits, the presence of living spirochetes may be demonstrated; for this reason *no rabbit can be regarded as having completely recovered from syphilis in chemotherapeutic investigations unless this lymph-gland test proves negative.*

As a general rule, rabbits are selected for chemotherapeutic experiments when the lesions are active and spirochetes are to be found by dark-field

examination. After the administration of the medicament, the results may be evaluated by noting and recording the following data: (*a*) The time when spirochetes have disappeared by thorough and repeated dark-field examinations of different lesions and different areas of the same lesion; (*b*) the clinical regression of the lesion or lesions; (*c*) the presence or absence of exacerbations of the old lesions and development of new lesions over a period of at least 2 months; (*d*) finally, the results of inoculation of an emulsion of lymph-glands into a fresh animal and its observation for a period of at least 2 months for the development of syphilis.

The complement-fixation test as a criterion of cure in rabbit syphilis is not reliable. In the first place, the serums of a large percentage of normal rabbits give positive Wassermann reactions as first discovered by Schilling and Hoesslin[23] and since amply confirmed by Casselman, Trist and myself[22] and others. By the use of a quantitative test employing graded amounts of serum, it can be shown that the serums of syphilitic rabbits acquire an increased power for complement fixation with tissue extracts, but I have frequently observed negative reactions with the serums of rabbits in the latent stages of syphilis when lymph-gland inoculation into fresh animals has disclosed the presence of living spirochetes.

Venereal Spirochetosis of Rabbits.—Apparently this condition of normal stock rabbits may be mistaken for the syphilitic lesions of the penis and anus. Ross and Bayon[24] in England, were the first to call attention to this condition associated with a spiral organism morphologically indistinguishable from *Spirochæta pallida* of human origin. Soon afterward, Artz and Kerl,[25] Jacobsthal,[26] Schereschewsky[27] and Klarenbeek[28] published observations of a similar nature. Brown and Pearce[29] state that they have never encountered the infection. Noguchi,[30] however, has recently encountered the condition in nine female and two male rabbits in the so-called normal stock of the Rockefeller Institute and has described the disease as follows:

"The lesions are situated on the vulva or prepuce and appear as scaly, papular, somewhat congested spots or patches, slightly elevated from the surrounding muco-cutaneous surface; they are not indurated to any marked extent as are usually the lesions produced by *Treponema pallidum* in similar regions. There is at first no exudate, but mechanical irritation of any kind induces a hyperemic condition of the lesions, and the dry scales fall off, leaving an exposed, granular surface. The exudate dries rapidly and forms a shining crust, dark gray or yellowish, removal of which is followed again by exudation, appearance of minute ecchymoses, and crust formation. In chronic cases the lesions may cover the entire genital region and extend to the anus.

"The minute initial papules, as well as the advanced lesions with crust, contain very large numbers of organisms perhaps slightly coarser and longer than the average type of *Treponema pallidum*. The length varies from 10 to 18 microns, the majority being from 10 to 12 microns for the average *Treponema pallidum*. Individuals as long as 30 microns have been observed (specimens of *Treponema pallidum* as long as 24 microns have occasionally been encountered in experimentally infected rabbits). The width is about 0.25 micron, spiral amplitude from 1 to 1.2 microns, spiral depth from 0.6 to 1 micron; the spirals, from eight to twelve in number are regular and deep. Rapid rotation and occasional bending at the middle are observed, but no vibratory or lashing movements. The organism belongs to the genus *Treponema*, and may be designated as *Treponema cuniculi*."

Noguchi attempted to transmit the disease by mating infected animals with normal animals and was successful in one instance. Schereschewsky,[31] however, was able to transmit the disease sexually with great ease, and utilized the method of transmission for testing the prophylactic value of different ointments.

Nichols and Walker[32] have likewise failed to find evidences of this disease among normal rabbits, but verified Noguchi's observations with a female animal furnished by Dr. Noguchi. According to Nichols and Walker, how-

ever, "natural spirochetosis of rabbits need not be a serious complicating factor in work on syphilis in rabbits, for the following reasons: (*a*) In natural spirochetosis the lesions occur on the penis and not on the scrotum. Gland transfers are negative. (*b*) A scrotal lesion can be produced by inoculation, but it can be distinguished from that of *Treponema pallidum* infection by its course. (*c*) In studies of generalized syphilis supposed to involve the genitalia, and in sexual transmission experiments, *Treponema cuniculi* may be a serious complicating factor."

More recently Warthin, Buffington and Wanstrom[33] have reported a thorough series of studies in eighteen cases of rabbit spirochetosis and regard cuniculi spirochetosis as "a local disease of epithelial surfaces, the clinical course and local and general pathology of which do not in any way resemble those of syphilis. It should not be called "rabbit syphilis," and the term "paralues cuniculi" should also be discarded. The spontaneous rabbit disease can be easily differentiated from pallida infections by its morphology, as shown in silver-agar cover-glass smears, and by the pathology of the lesions."

I have never seen the disease among rabbits in Philadelphia and very much doubt that investigations in experimental rabbit syphilis in the United States at least has been appreciably influenced or compromised by this infection. Apparently the disease is more common in Europe. At any rate it is necessary to choose animals with care for experimental inoculation with *Sp. pallida* or *Sp. pertenuis*, and to carefully study and reject any that show infections about the genitalia and anus.

Experimental Frambesia (Yaws) of the Rabbit.—Shortly after the discovery of *Spirochaeta pallida* Castellani discovered *Spirochaeta pertenuis* as the cause of frambesia, a disease of tropical countries variously designated as "yaws," "pian," "coko," etc. The similarity between the two spirochetes is so close that differentiation is only possible by cross immunity tests.

In 1907, Neisser, Baermann and Halberstadter,[34] succeeded in transmitting the disease to the higher apes in Sumatra and demonstrated that it was a distinct entity rather than a tropical form of syphilis. In 1909, Nichols,[35] succeeded in infecting the eyebrow of a monkey (*Macacus rhesus*) by rubbing an abrasion with a piece of yaw nodule removed from a human subject. Nichols then succeeded in inoculating the testicles of rabbits with material from the monkey and thereby opened up a means for further immunological and chemotherapeutic studies in frambesia. A little later, Nichols[36] also succeeded in producing scrotal lesions (chancres) with *spirochaeta pertenuis* and since then other investigations have confirmed his observations. Both Nichols and Schamberg and Klauder[37] have failed to infect rabbits by inoculation of the anterior chamber of the eye. According to Nichols, large white rabbits are to be preferred to small and immature animals; gray, brown and black animals are less likely to become infected.

The testicles are inoculated by injecting an emulsion of yaw material containing large numbers of actively motile spirochetes obtained either from a human case of yaws or an infected rabbit, in exactly the same manner as described for the production of rabbit syphilis; or a small bit of the yaw tissue may be planted into the substance of the testicle or just beneath the scrotal skin, but injections of the emulsion directly into the substance of the testicle yields a higher percentage of successful inoculations.

Both Nichols and Schamberg and Klauder observed that only 50 per cent. of rabbits are successfully inoculated direct with human material; it is well therefore, to always inoculate at least 6 rabbits for the primary "takes" in order to insure 2 or 3 successful inoculations. Later a higher percentage of "takes" are secured by passage of the spirochete from rabbit to rabbit as in the propogation of *Spirochæta pallida*.

Direct inoculation of the rabbit testicle with human material is followed by a primary incubation of about 5 weeks; after several transfers in rabbits this period is shortened to 3–4 weeks, and even to 2 weeks as reported by Nichols. Lesions of the scrotum may develope in about 23 days, which is a much shorter incubation than in syphilitic chancers.

Both the testicular and scrotal lesions are almost indistinguishable from the lesions of syphilis (Fig. 17). Nodules develop varying in size from a pea to that of an olive, with necrosis of the tubules, infiltration of small lymphocytes and the production of new fibrous tissue (Nichols).

The organs are enlarged and edematous; a palpable node is present in each organ. A dark field examination of the serum obtained on puncturing each node disclosed many spirochetes.

It is known that in human frambesia the spirochetes may be found in the spleen, lymphatic glands, bone-marrow and sometimes in the blood. The distribution however, is seldom as extensive as occurs in syphilis, the cardio-vascular system for example, commonly escapes. The brain and spinal cord are likewise less liable to invasion with *Spirochæta pertenuis*. In yaws therefore, the spirochetes are more apt to invade the skin, mucous membrane of the nose and pharynx, the joints and periostium; Pearce and Brown[38] have recently described the various lesions with considerable detail.

Aside from the successful inoculation of monkeys and rabbits, yaws has not been transmitted to other animals as mice, rats and guinea-pigs.

FIG. 17.—TESTICULAR LESIONS OF RABBITS CAUSED BY SPIROCHAETA PERTENUIS. (Schamberg and Klauder.)

Methods for Determining the Spirocheticidal Activity of Substances in Vitro.—As stated in Chapter II, compounds are sometimes prepared in the course of chemotherapeutic studies which possess such high toxicity when administered to living animals, that sufficient amounts cannot be administered to appreciably influence a spirochetic infection. Under these conditions it is sometimes necessary to determine the spirocheticidal activity of a medicament *in vitro* or by a combined *in vitro in vivo* test.

Technic of Microscopical Methods.—With *Sp. novyi* (American relapsing fever) I have successfully employed a method exactly similar to that described in Chapter X for direct microscopical tests with trypanosomes. The blood of an infected mouse is employed and the highest dilution of the medicament is determined which produces complete loss of motility of the spirochetes. As is true of the trypanosome tests by this technic, the results are only approximately correct, because loss of motility of the spirochetes does not necessarily indicate their complete destruction.

With Spirochæta pallida direct microscopical tests may be conducted employing pure cultures in a field medium or emulsions of testicular tissue of rabbits showing sufficient numbers of spirochetes. The latter is prepared by removing a syphilitic testicle at a time when dark-field examination shows the presence of large numbers of actively motile organisms. The tissue is cut into small pieces and throughly rubbed up in a mortar with a few cubic centimeters of warm saline solution. This emulsion is now briefly centrifuged to remove the tissue fragments and the supernatant fluid employed. The culture or tissue preparation should contain such numbers of spirochetes that each microscopic dark field shows at least 20 to 30 organisms.

Dilutions of the medicament are prepared in test-tubes or vials and one small loopful (3 mm. loop) of each placed in the center of a thin cover-glass. To each is now added a loopful of the spirochete suspension followed by thorough mixing. The cover-glass is then placed on a thin microscopical slide and the material evenly spread. It is necessary to work with small amounts of material in order not to float the cover-glass with the production of cross currents when each is examined by dark-field illumination. Generally three cover-glasses can be placed on one slide. Each may be ringed with a mixture of vaselin and paraffin and kept at room temperature or at 37°C. in a small oven. Controls are

always included in which a loopful of the spirochete suspension is mixed with a loopful of saline solution.

Each preparation is examined by dark-field illumination at the end of 5, 10, 15 and 30 minutes; longer periods are sometimes employed providing the controls show the presence of motile spirochetes. The results are evaluated according to the highest dilution of medicament causing loss of motility of the majority or all of the spirochetes in a given period of time. These results do not, of course, necessarily indicate the complete destruction of the organisms.

Technic of Combined in Vitro in Vivo Method.—This test is conducted in exactly the same manner as the trypanosome test described on page 216. In working with *Sp. recurrentis*, the blood of a mouse is employed or a mixture of the bloods of several mice showing large numbers of actively motile apirochetes. Care should be exercised against using the blood of an animal in which the spirochetes are agglutinated and feebly motile or quiescent, which is generally observed just before or during a crisis of the infection. Mixtures of varying dilutions of the medicament and the citrated spirochete blood (0.5 c.c. of each) are made in small sterile test-tubes as previously described and kept in a water-bath. Controls are always included of mixtures of citrated blood (0.5 c.c.) and saline solution (0.5 c.c.). Since saline solution is toxic for these spirochetes the period of exposure should not be longer than 30 minutes when 0.5 c.c. of each mixture is injected into mice intraperitoneally and the animals observed for infection with daily examinations of the tail blood. As a general rule, tests of this kind employing *Sp. novyi* have not yielded as regular or clear-cut results as have been observed with *Tr. equiperdum* and *Tr. brucei*.

An exactly similar test has been employed with *Spirochæta pallida*. An emulsion of rabbit syphilitic testicle is prepared in saline solution and briefly centrifuged. The supernatant suspension of spirochetes should show at least 20 organisms per dark field.

Varying dilutions of the medicament in amount of 0.5 c.c. each are mixed in small sterile test-tubes with 0.5 c.c. of spirochete suspension and the mixtures kept in a water-bath for a given period of time, when 0.5 c.c. of each mixture is injected into the testicles of rabbits and the animals observed for the development of syphilis. Experiments have shown that under these conditions the spirochetes remain alive and infective in the controls (0.5 c.c. of saline solution and 0.5 c.c. of spirochete suspension) for several hours.

One drawback to the method is that some compounds in a spirocheticidal dilution are capable of exciting inflammatory changes in the testicle. Furthermore, the action of a medicament may be continued after the mixtures are injected, as previously stated in connection with the trypanosome test by this method; for this reason I have designated the test as a combined *in vitro in vivo test*.

Technic of in Vitro Culture Method.—With the spirochetes that have been successfully isolated and cultivated *in vitro* as *Spirochæta pallida, Spirocheta refringens, Spirocheta microdentium*, etc., it is possible to conduct *in vitro* tests after the technic employed by Akatsu and Noguchi.[39] These tests may be of a spirochetostatic or spirocheticidal character.

Technic of Dark-field Examination for Spirochetes.—While the spirochetes of human and fowl relapsing fever may be readily found by simple microscopic examination of the blood, *Spirochæta pallida*, because of its low refractive index, is seen when alive with difficulty by the ordinary microscope. By far the most successful and easily applied method of finding the organism in syphilitic lesions of the rabbit and human subject, is by the use of the dark-field method. The technic of this examination is as follows:

1. The apparatus required is: (*a*) *A powerful light* with lens to focus the rays on the mirror of the microscope. The usual arc light shown in Fig. 18 is excellent; a drawback is that it requires frequent adjustment of the carbons unless an automatic lamp is used. Outfits equipped with madza lamps are also available and possess the advantage of furnishing a steady light with less heat. (*b*) *A funnel stop* for the ordinary $\frac{1}{12}$th oil-immersion lens to reduce the light and (*c*) *A dark-field condenser*. This condenser may be purchased fitted to be screwed into the substage after removal of the usual Abbé condenser or in the form of a slide to be clamped to the stage of the microscope over the ordinary condenser. When much dark-field work is required it is advisable to provide a microscope fitted with the special substage condenser to be used alone for these examinations.

2. Thin or medium slides should be used; thick slides do not permit focussing of the dark field. The slides should be perfectly clean and preferably free of scratches. Thin cover-glasses are also required.

3. In the examination of a chancre (human or rabbit), the lesion should be superficially cleansed, in order to remove the many contaminating organisms on the surface. Most of the surface crust should be removed and a little serum squeezed out from the deeper tissues.

A drop or loopful of this material may be placed on the slide; it is sometimes advantageous to mix it with a drop of distilled water, but *care should be exercised not to use too much material or diluent in order to prevent floating of the cover glass* and the setting up of cross

currents which prevent proper examination. For the examination of testicular lesions in rabbits or enlarged lymph-glands in rabbits or human subjects, material may be secured by puncturing with a sterile No. 26 or No. 22 needle fitted to a 1 c.c. syringe and aspirating a sufficient amount of secretion for this examination.

4. A drop of immersion oil is placed on the under surface of the slide (this is preferable to putting a drop of oil on the condenser), and another drop on the cover-glass. The slide is then gently placed on the condenser so that the bottom drop of oil spreads evenly without bubbles between the under surface of the slide and the surface of the dark-field condenser.

5. The light should now be centered. This is accomplished while the examiner looks through the low power of the microscope. By focussing up and down, concentric rings of light can be seen and brought to center on the preparation. This centering of the light rings is accomplished by shifting the condenser from side to side by means of the lateral screws, and up and down by means of the vertical condenser screw. By these manipulations the center ring of light becomes a point of light in the middle of the preparation and this adjustment may be necessary because of variations in the thickness of slides. After this has been accomplished, the immersion lens is gently let down until it touches the oil on the top of the cover-glass and adjustment is made with the fine adjustment of the microscope. If a microscope fitted with a dark-field condenser is reserved solely for work of this kind, removing the necessity of changing from the ordinary to the dark-field condenser, and if slides of uniform thickness are employed, centering the light is not ordinarily required but the dark field found by manipulation of the mirror until the proper lighting is secured.

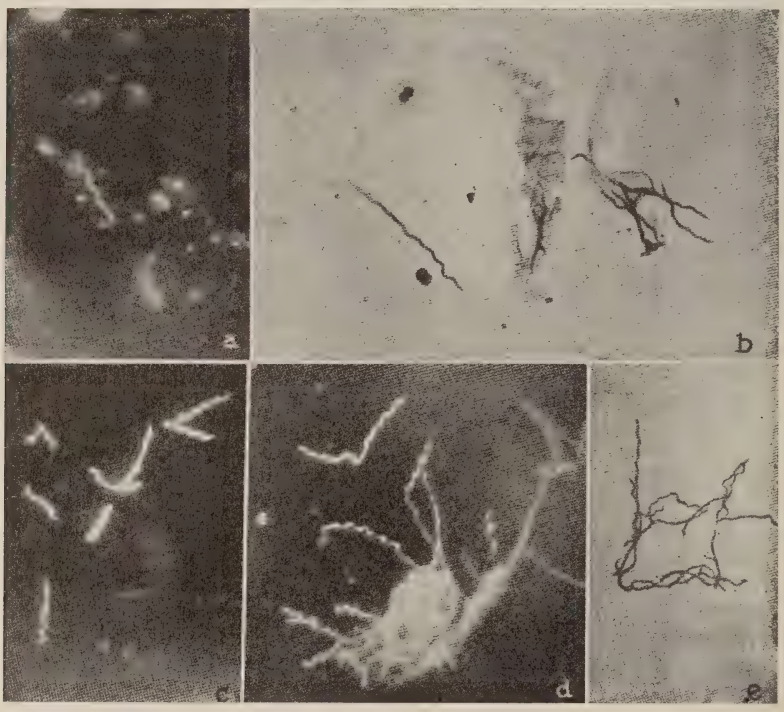

FIG. 20.—SPIROCHAETA REFRINGENS.

6. Spirochetes and other formed elements appear as brilliant white objects (Fig. 19). In rabbits with syphilitic scrotal and testicular lesions no difficulty is ordinarily experienced in finding the organisms. In the examination of human lesions and particularly those in the mouth and throat, due care must be exercised against mistaking other spirochetes as *Sp. refrigens* (Fig. 20) *Sp. macrodentium*, *Sp. microdentium*, etc., for *Sp. pallida*.

Technic of Fontana Staining Method for Spirochetes.—While the spirochetes of syphilis and yaws are best detected in the primary lesions by the dark-field method described above, staining methods are occasionally useful

and among the best in my experience is the improved Fontana method as follows:

(1) Films are prepared by placing the material in a drop of distilled water on a slide, spreading and drying in the air. (b) Films may be now fixed by passing over a flame or better by placing in Ruge's fluid for 1 to 5 minutes (glacial acetic acid, 1 c.c.; formalin, 20 c.c. and distilled water, 100 c.c.). (c) The films are now thoroughly washed in running top water when the mordant solution (tannin, 5 grams; phenol, 1 gram and distilled water, 100 c.c.) is poured and warmed until vapor arises for 30 seconds, followed by washing in running water for 15 to 30 seconds. (d) Without drying the silver nitrate solution is applied (silver nitrate, 1 gram; distilled water, 400 c.c. Add ammonia water until slight turbidity results. If excess of ammonia is introduced, the fluid becomes clear again and cannot be used—a trace is all that is required) and heated until steam arises for 30 seconds followed by washing in tap water and drying. If permanent preparations are desired, they must be mounted in xylene balsam; cedar oil causes fading of the spirochetes. The jet-black spirochetes stand out prominently on the clear yellowish background and appear much thicker than when stained by the Giemsa method.

CHAPTER XXII

SPIROCHETICIDAL PROPERTIES OF DYES

Since the science of chemotherapy began with the investigations of Ehrlich and his collaborators on the action of various dyes in experimental trypanosome infections of mice, it is not surprising that these substances were likewise among the first employed in the experimental chemotherapy of spirochetic infections and especially those transmissible to the smaller animals, as *Sp. obermeieri* infections of mice.

Dyes in the Chemotherapy of Experimental Relapsing Fever.—Vassel[1] was among the first to discover that of the benzidine dyes, trypan-red and amino-naphthol-disulphonic acid were slightly effective in mice infected with the spirochete or spirillum of relapsing fever (*Sp. obermeieri* or *Spirillum recurrentis*). Manteufel[2] also noted slightly curative effects if the dyes were injected at the same time as the organisms. If, however, the infection was given twenty-four hours headway, the dyes had practically no influence upon the infection.

In Hata's[3] investigation the plan was to first determine the highest dilutions of each dye dissolved in alcohol or water and diluted with saline or cane sugar solution, capable of destroying the motility of the organisms in the test-tube as determined by microscopical examinations. As a general rule, loss of motility indicated death of the organisms as injection of the mixtures of blood and dye into mice were generally followed by negative results, or, in some instances, a few spirochetes would appear in the blood of the mice after long periods of incubation.

Animal tests were conducted by infecting mice with *Sp. obermeieri* as described in the preceeding chapter, followed about twenty-four hours later by the subcutaneous or intramuscular injection of the medicament in varying amounts according to body weight. In experiments of this kind with more than 200 dyes of the thiazin and benzidine series and other varieties, the results were generally negative, insofar at least as the animal tests were concerned. Dyes like *methylene-blue* and *methylene-violet* were able to kill *Sp. obermeieri* in the test-tube in dilutions as high as 1:6,000,000 to 1:20,0000,000 but when injected into mice in doses varying from 0.080 gm. to 0.250 gm. per kilo of weight, were without effect upon the development and course of the spirochetosis.

Trypan-red and *trypan-blue*, which as noted in Chapter XI possess well marked trypanocidal properties, are practically devoid of spirocheticidal activity. In Hata's experiments dilutions as low as 1:200 were unable to destroy *Sp. obermeieri* in the test tube and were likewise without effect in mice.

Dyes in the Chemotherapy of Experimental Hen Spirillosis and Rabbit Syphilis.—Hata states that the dyes employed in his investigation had the same effect upon *Sp. gallinarum* in the test tube as upon *Sp. obermeieri*, but the results of animal tests with hen spirillosis were so largely of a negative character as hardly worth mentioning.

These results afford almost complete evidence that the dyes do not possess demonstrable spirocheticidal activity *in vivo*, because of all spirochetic infections hen spirillosis is most easily influenced and cured.

The only experiments conducted with *Sp. pallida* infections were reported by Neisser[4] who treated 86 monkeys at the time of inoculation or a few days afterward with various dyes and with practically negative results in all. Twelve animals received subcutaneous or intravenous injections of *methylene-blue* in dose of 0.2 gm. per animal and eleven about 0.7 gm. by oral administration and all developed syphilis. Eight animals received intravenous infections of *giemsa stain* in dose of 0.4 gm. per animal and all developed the disease. Eight animals received intravenous injections of *fuchsin* in dose of 0.14 gm. per animal and

all developed syphilis; twenty-two additional animals were treated with *parafuchsin* by oral administration in oil and all developed the disease. Eight animals treated with the subcutaneous injection of *trypan-red* in dose of 3 to 5 c.c. of a 2½ per cent. solution developed syphilis.

It may be stated, therefore, that while the dyes are of some importance in relation to the chemotherapy of bacterial and trypanosome infections, little or nothing is to be expected of them in the chemotherapy of syphilis or other spirochetic infections. In other words the various dyes subjected to study including those possessing trypanocidal activity in infected animals, are practically without demonstrable spirochetocidal effects in animals despite the high spirocheticidal activity of some of them in the test tube. It is possible, however, that future researches will show them to possess more importance in the chemotherapy of spirochetosis than now surmized if they can be made to act as the carriers of more active substances into diseased tissues by reason of selective affinity for these.

Mechanism of the Spirocheticidal Activity of Dyes.—Very little is known of the exact mechanism whereby the dyes actually bring about the destruction of spirochetes. *In vitro* the organisms (*Sp. obermeieri* and *Sp. gallinarum*) become slightly stained, lose motility and undergo morphological changes ending in complete solution and total disappearance. As a general rule, complete loss of motility means death, but sometimes such spirochetes are still infective although the incubation period following inoculation before the organisms appear in the blood is apt to be prolonged and the infection less virulent. It would appear therefore, that *in vitro* damage may be done to the proliferative mechanism of the spirochetes from which they but slowly recover.

Probably *in vivo* the spirocheticidal dyes act directly upon the parasites. There is no direct evidence of the production of new compounds in the blood or tissues such as processes of oxidation or reduction with the organic arsenical and antimonyl compounds. However, the fact that some dyes are spirocheticidal *in vivo* and not *in vitro* suggests that a transformation occurs *in vivo* with the production of a new product of the dye or the production of a new combination product of the dye with a tissue constituent.

Influence of Dyes upon the Development of Immunity in Spirochetosis. As stated in Chapter XI Ehrlich and Shiga observed in 1904 that after the cure of *Tr. brucei* infections of mice with trypan-red and other dyes, the mice were refractory to re-infection with this strain for about ten days. Terry and others confirmed these observations and showed that this temporary immunity was not due to the presence of unexcreted dye.

Does a similar immunity develop in mice or fowl after the cure of experimental *Sp. obermeieri* and *Sp. gallinarum* infections? Investigations along these lines have been hampered by the fact that in both infections an immunity develops independent of drug treatment which tends to become stronger with each relapse.

Working with *Sp. novyi* in mice, I have found that infected mice cured with a single dose of trypan-red are more difficult to re-infect during the following fifteen days than untreated control mice during their first relapse. Mice treated with dye alone could be infected 60 hours later with the same amount of spirilli-blood as control mice showing that the influence of unexcreted medicament does not last longer than this time, when an ordinary curative dose is given by intraperitoneal injection. Hata states that mice cured by a single injection of a dye early in the course of relapsing fever are susceptible to re-infection about 60 days later, but require a larger number of spirochetes (*Sp. obermeieri*) for infection than control mice to overcome the immunity. This indicates that the immunity does not last longer than 60 days and I believe it is of much shorter duration when complete cure has been effected. In case of incomplete cure the animals are highly refractory to re-infection, but this is due to the presence of living spirochetes in the tissues even though the blood is apparently free, and not to any influence on the part of the dye.

I believe it may be stated, therefore, that the administration of curative doses of trypan-red and presumably of other spirocheticidal dyes, aids in engendering a state of temporary resistance or immunity to re-infection. This is probably not due to the influence of the dyes upon the antibody producing tissues, because investigations in trypanosomiasis along these lines have yielded negative results. Rather the dyes release from spirochetes by reason of their spirocheticidal activity, active antigenic principles which engender the production of the immune substances.

Furthermore, there is no reason for believing that this immunological process has any influence upon the cure of experimental spirochetosis by single large doses of any dye; *therapie magna sterilisans* is due to the direct action of the dye or its products upon the spirochetes because there is not sufficient time for antibody production. But in the treatment of chronic infections with repeated doses of a dye compound it is entirely likely that the production of immune principles aid in bringing about a cure.

Acquired Resistance of Spirochetes to Dyes.—As discussed in Chapter XI trypanosomes readily acquire resistance to various dyes and especially parafuchsin and trypan red when infected mice or rats are treated with sub-curative doses of these compounds. The surviving trypanosomes become resistant to the dye and this "fastness" may be increased by additional treatments and transfers, the state of resistance being transmissible.

Similar investigations with the spirochetes does not appear to have been reported. Several years ago I worked with *Sp. novyi* and trypan-red and after seven transfers thought that the strain had acquired a definite increased resistance to this due, but owing to the irregularities of relapsing fever infections of mice the experiments were not as definite and decisive as similar experiments in trypanosomiasis. However, a conservative estimate of the experiments has lead me to the conclusion that *Sp. novyi* may acquire a "resistance" or "fastness" to dyes and it is highly probable that the same is true of other spirochetes.

CHAPTER XXIII

TOXICITY AND SPIROCHETICIDAL PROPERTIES OF ARSENICAL COMPOUNDS

Shortly after the discovery of the trypanocidal activity of atoxyl, Uhlenhuth and his associates conducted similar studies with atoxyl and mercury in the chemotherapy of spirochetic infections. This was quickly followed by the investigations of Ehrlich, Hata and others, who derived great encouragement by the fact that some new arsenical compounds without demonstrable trypanocidal properties were found to favorably influence spirochetic infections and especially relapsing fever of mice and spirillosis of chickens. From the standpoint of practical results, therefore, studies in the chemotherapy of

organic arsenical compounds in experimental spirochetic infections have been among the most fruitful.

Arsenical Compounds in the Chemotherapy of Experimental Relapsing Fever.—Most experimental work has been conducted with mice infected with *Sp. obermeieri* (*Sp. recurrentis*), the cause of European relapsing fever; *Sp.duttoni* (African relapsing fever) and *Sp. novyi* (American relapsing fever) have been less frequently employed and *Sp. carteri* (relapsing fever of India) does not appear to have been used at all.

In practically all of the early work conducted by Hata in collaboration with Ehrlich, mice were employed, the maximum tolerated and minimum curative doses being determined by injecting the medicaments subcutaneously. As a general rule, the drug was administered 24 hours after the intraperitoneal injection of *Sp. obermeieri*, although the preventive or prophylactic activity of many of the compounds was likewise determined by giving the drug 24 to 48 hours or more before infection.

In my experiments such inorganic compounds of arsenic as *arsenious acid*, *sodium arsenate* and *sodium arsenite* had no influence at all upon the course of *Sp. novyi* infections of mice when these compounds were administered by subcutaneous injection and in doses as large as the maximum tolerated amounts.

The effects of organic arsenical compounds in general upon *Sp. obermeieri* infections of mice are much less powerful than those produced by these compounds upon *Tr. equiperdum* infections of rats. Even *arsphenamin* (*salvarsan*) has an index of but 2.7 for *Sp. obermeieri* infections as compared with an index of 15 or higher for various trypanosome infections.

The pentavalent compounds are much less spirocheticidal in these infections than the trivalent compounds. In trypanosomiasis some pentavalent compounds and especially derivatives of the arsonic acids, as amino-oxyphenyl arsonate and tryparsamid,[1] are highly trypanocidal, but these as well as atoxyl and arsacetin are much less effective in experimental relapsing fever.

Best results have been observed with the arsenobenzene compounds, as *arsphenamin* and *neoarsphenamin*. The chemotherapeutic index of arsphenamin is as follows, the compound being administered to the mice by subcutaneous injection:

$$\frac{\text{Maximum tolerated dose: 0.170 gm. per Kilo}}{\text{Minimal curative dose: 0.06 gm. per Kilo}} = 2.8$$

The chemotherapeutic index of neoarsphenamin is about as follows:

$$\frac{\text{Maximum tolerated dose: 0.350 gm. per Kilo}}{\text{Minimal curative dose: 0.012 gm. per Kilo}} = 2.9$$

Neoarsphenamin, therefore, tends to have a slightly higher index than arsphenamin and this is true in experimental trypanosomiasis. It may be noted in passing that the percentage of arsenic in the different compounds bears no constant relation to either toxicity for the mice or curative activity.

The cure of experimental relapsing fever of mice and rats is, therefore, more difficult than the cure of trypanosome infections and likewise, as will be shortly shown, more difficult than the cure of *Sp. gallinarum* infections of chickens and *Sp. pallida* infections of rabbits. Of course, small amounts of the various medicaments may suffice for temporarily removing *Sp. obermeieri* and *Sp. novyi* from the blood of mice, but the amounts required for effecting complete cure, as determined by re-infecting the mice 60 days later, are much higher. In general terms, the cure of experimental relapsing fever

of mice is more difficult to effect than the cure of experimental trypanosomiasis or other spirochetic infections of the lower animals and affords an additional example of the important influence exerted by the parasite employed upon chemotherapeutic investigations.

Arsenical Compounds in the Chemotherapy of Experimental Chicken Spirillosis.—Probably the first experimental spirochetic infection to be treated with an arsenical compound was hen spirillosis (*Sp. gallinarum*) with *atoxyl* by Uhlenhuth, Gross and Bickel[2] in 1907.

These investigators determined that the lethal dose for chickens by intramuscular injection was about 0.5 gm. per kilo of weight. As a general rule the injection of 0.05 gm. per kilo proved curative even when injected 48 hours after infection and when numerous spirochetes were present in the peripheral blood. Likewise, when this amount was injected before or simultaneously with the spirochetes, infection did not usually take place. When administered by mouth 0.1 gm. per kilo also proved curative.[3]

A little later Uhlenhuth and Manteufel[4] combined atoxyl and mercury in order to permit the treatment of human syphilis simultaneously with arsenic and mercury; this *mercuric arsanilate* was found to contain 31.65 per cent. mercury and 23.75 per cent. arsenic. The compound was more toxic than atoxyl and the curative dose remained about the same.

Following these investigations Hata determined the toxicity of a number of new arsenical compounds for the chicken by intramuscular injection and likewise their curative activity in *Sp. gallinarum* infections. In a general manner it was noted that the maximum tolerated doses of the various compounds was slightly greater for chickens by intramuscular injection than for mice by subcutaneous injection and that the curative activity of all compounds was very much greater for *Sp. gallinarum* than for *Sp. obermeieri.* Even atoxyl, which possesses very little prophylactic and curative value in *Sp. obermeieri* infections, is distinctly curative for *Sp. gallinarum* infections, yielding a chemotherapeutic index of about 5. Forneau and Levaditi[5] and Forneau[6] have reported that some of the *derivatives* of *phenylarsonic* and *arylarsonic acids* possess well-marked spirocheticidal activity, yielding chemotherapeutic indices of 5.

Jeanselme and Pomaret[8] have likewise reported that some of these phenylarsonic acid derivatives possess curative activity in hen spirillosis and rabbit syphilis; according to the latter a compound designated as 132 or *amino-arsenol phenol* is tolerated by chickens in dose of 0.150 gm. per kilogram of weight and is curative for *Sp. gallinarum* infections in dose of 0.0037 gm. per kilogram, yielding, therefore, an index of 40.

Doubtless these favorable results have been greatly aided by a marked tendency for the development of immunity and spontaneous cure in hen spirillosis. While this experimental infection is serviceable for eliciting minor degrees of spirocheticidal activity of new compounds, great care is required in the interpretation and evaluation of the results.

As is true in the treatment of trypanosomiasis and *Sp. obermeieri* infections, trivalent organic compounds of arsenic (arsphenamin and neoarsphenamin) are more active than pentavalent compounds; according to Sezary and Pomaret,[9] the curative activity of arsphenamin is 5 times and neoarsphenamin 3.3 times stronger in *Sp. gallinarum* infections than Fourneau's pentavalent compound acetyl-oxyamino-phenylarsinic acid,[190] although, when these substances are given orally instead of being injected intramuscularly or intravenously, the differences in curative activity are much less.

Arsenical Compounds in the Chemotherapy of Experimental Syphilis.—Owing to the larger size and expense of rabbits, the necessity of using a number of them for determining the toxicity and minimal curative doses of any medicament and the relatively long times required for the evaluation

of the therapeutic results, rabbit syphilis has not been as extensively employed in experimental chemotherapy as trypanosome infections. The earliest work in experimental syphilis was conducted with monkeys and necessarily was on a very limited scale. In rabbits the earliest chemotherapeutic investigations were conducted with experimentally produced syphilitic keratitis, but testicular lesions are now employed almost exclusively.

In many instances investigators have expressed the spirocheticidal activity of medicaments on the basis of rapidity of disappearance of *Sp. pallida* from the local lesions; as stated in the preceding chapter, however, the dose required to bring about these results may not be necessarily the curative dose, as spirochetes may still be found in the lymphatic glands. It is necessary, therefore, to examine the lymph-glands for spirochetes by additional animal-inoculation tests requiring more animals and still further delaying the time when the results of final tests will be known. Despite these economic and technical difficulties, the treatment of rabbit syphilis constitutes in the final analysis an almost necessary part of any chemotherapeutic investigation in syphilis.

Spirocheticidal Activity of Inorganic Compounds of Arsenic in Syphilis.—In *Sp. pallida* infections of monkeys Neisser[10] has observed that arsenious acid was without curative activity. Fifty-six monekys weighing roughly from 2 to 6 kilograms received intravenous injections of doses varying from 0.011 to 0.089 gm. per animal within 2 to 4 days after inoculation or after the development of the primary lesion; in practically no instance was syphilis prevented and at best but slight curative properties were apparent.

Toxicity and Curative Activity of Atoxyl (Sodium Arsanilate) in Experimental Syphilis.—From the historical standpoint, *atoxyl* is of great interest in the treatment of syphilis because it was the first organic compound of arsenic to be used for the prophylactic and curative treatment of experimental syphilis of monkeys and rabbits.

Metchnikoff[11] showed in 1907 that atoxyl in dose of 0.3 to 0.5 gm. per kilo of weight prevented syphilis of apes if administered within 15 days of the time of inoculation. Similar results were observed by Salmon[12] with intramuscular injections of atoxyl in dose of 0.05 to 0.1 gm. per kilo.

Uhlenhuth, Hoffman and Roscher[13] observed the curative value of 10 to 25 doses of atoxyl in amounts of 0.05 to 0.1 gm. injected intramuscularly every 2 or 3 days in syphilitic apes and rabbits, and, in experiments conducted with Weidanz,[14] found this compound superior to mercuric chlorid in the treatment of syphilitic keratitis of rabbits. Levaditi and Yamanouchi[15] also found that atoxyl in dose of about 0.1 gm. per kilo injected subcutaneously prevented the development of syphilitic keratitis in rabbits. These results lead to the use of atoxyl in the treatment of human syphilis, until it was discovered that the compound produced changes in the optic nerve with disturbances of vision.

As a matter of fact, the curative activity of single doses of atoxyl in scrotal or testicular syphilis of rabbits is not very high. In my experiments, the maximum tolerated dose of pure compounds for rabbits by intravenous injection was about 0.120 gm. per kilo and the minimal curative dose varied from 0.030 to 0.060 gm. per kilo, yielding chemotherapeutic indices of 2 to 4. Smaller doses sufficied for reducing the numbers of spirochetes in the lesions with subsidence of the inflammatory changes, but only maximum amounts were curative in single doses.

Neisser[16] in 1909–1910 administered to 47 monkeys by intravenous or subcutaneous injection of 0.05 to 1.0 gm. per animal, at the same time as inoculation with syphilis virus; of these, 4 developed primary lesions and 43 did not. Neisser also treated 63 additional animals with atoxyl in dose of 0.05 to 1.8 gm. per animal (2 to 6 kilograms) after the development of primary lesions; of these, 25 were not cured, as after the lesions disappeared re-inoculation was positive in all. Thirty-six animals were probably cured as re-inoculations were negative, while the results were doubtful with two animals.

Toxicity and Spirocheticidal Activity of Arsenophenylglycin, Arsacetin and Allied Compounds in Experimental Syphilis.—Ehrlich and Hata did not employ experimental syphilis on a large scale in their chemotherapeutic investigations. Most of the curative tests were conducted with mice infected with *Tr. brucei* or *Sp. obermeieri* and chickens with *Sp. gallinarum.*

Hata found the curative activity of *arsenophenylglycin* for scrotal syphilis of rabbits to be about 0.15 gm. per kilo by intravenous injection, and since this trivalent arsenical is tolerated in dose of about 0.200 gm. per kilo, the chemotherapeutic index is only 1.6, although at one time it was thought worthy of trial in the treatment of human syphilis. Neisser[17] treated 18 monkeys with 3 to 7 injections of arsenophenylglycin, totalling 0.15

to 0.7 gm. per animal, at the same time as inoculation with syphilis virus; of these, only one developed a primary lesion while 17 escaped. Three animals were treated with 0.3 gm. and 5 more with arsenophenylglycin plus 0.1 gm. atoxyl eight days after inoculation; all escaped syphilis. Thirty-five monkeys were treated after the development of primary lesions with 0.05 to 0.9 gm. per animal; of these, 29 were probably cured. Neisser observed the rather high toxicity of this compound for both monkeys and human subjects. Neisser also treated 24 monkeys with 0.2 to 0.5 gm. of *arsacetin* per animal at the time of inoculation with virus; of these, 2 developed syphilis and 22 escaped. Of fourteen additional animals treated with 0.35 to 0.7 gm. per animal after the development of syphilis, cure was effected in ten as re-inoculation was positive, whereas in the remaining four animals re-inoculation was doubtful or negative and indicative of failure of cure.

Sixteen monkeys were treated with *sodium-p-oxy-phenylarsenate* (*phenarsol*); the dose was 0.05 to 0.39 gm. per kilogram injected 3 or 4 days to several weeks after inoculation. Twelve animals survived and of these 9 developed primary lesions and 3 escaped. Of 4 additional animals treated with 0.05 to 0.36 gm. per kilogram after the primary lesions had developed, 2 were cured as shown by subsequent re-inoculation.

Seven monkeys were treated with *sodium-p-carbamino-arsenate* ("*asuran*"); the doses were 0.125 to 0.269 gm. per kilogram given about the time of inoculation; 6 escaped infection while 1 developed a primary lesion.

Seven monkeys were treated with *sodium acetyl-anthranilarsenate* ("*arsanthran*"); the doses were 0.1 to 0.48 gm. per kilogram about 3 to 4 days after inoculation; 6 developed primary lesions and 1 escaped. Three more animals treated after the development of primary lesions were not cured.

Levaditi and Navarro-Martin[18] treated syphilitic rabbits with sodium salt of *acetyl-oxyphenylarsonic acid* (189); the maximum tolerated dose was 0.4 gm. per kilogram by subcutaneous injection, while 0.175 gm. was curative, yielding a chemotherapeutic index of 1:4.

Toxicity and Spirocheticidal Activity of Arsphenamin (Salvarsan) in Experimental Syphilis.—Hata observed that the minimal curative dose of *salvarsan* (*arsphenamin*) for scrotal syphilis of rabbits was from 0.010 to 0.015 gm. per kilo and the investigations of Kolle[19] and myself have amply confirmed this work. Much smaller doses suffice for causing the spirochetes to disappear from the local testicular lesions; Nichols,[20] for example, found 0.0045 gm. per kilo sometimes sufficient for this purpose, but amounts less than 0.010 gm. per kilo are seldom sufficient for a permanent cure with sterilization of the lymph-glands.

Kuznitsky,[21] working with Neisser, treated 2 monkeys with subcutaneous injections of 0.025 gm. per kilogram of salvarsan in alkaline solution, several days before inoculation; both of these animals developed primary lesions. Three more animals were treated with 0.025 gm. per kilogram in neutral suspension at the time of inoculation and all escaped infection. Ten more animals were treated 2 to 223 days after the development of primary lesions with 0.025 gm. per kilogram in alkaline solution by intramuscular injection; 5 were apparently cured, as re-inoculations were successful, while 3 were not cured and the results doubtful in 2. Of 2 additional animals treated with 0.015 gm. per kilogram by intravenous injection, 1 was cured (re-inoculation positive) and 1 was not cured (re-inoculation negative).

According to Hata and Kolle the chemotherapeutic index of salvarsan is about 10 expressed as follows:

$$\frac{\text{Maximum tolerated dose: 0.100 gm. per Kilo}}{\text{Minimal curative dose: 0.010 gm. per Kilo}} = 10$$

With American-made arsphenamin (salvarsan) I have found, however, that the toxicity is generally less (0.110 to 0.0140 gm. per kilo) and the curative activity may be slightly greater. Some lots have been curative in amounts as low as 0.006 gm. per kilo, although the majority have required the administration of 0.010 to 0.012 gm. per kilo to effect complete sterilization of the lymphatic system. The chemotherapeutic indices of American-made arsphenamin may vary, therefore, from 10 to 20.

Hata also determined the spirocheticidal activity of "*arsenoxid*" which is supposed to form by oxidation in solutions of arsphenamin; while this substance is 6 to 7 times more toxic than arsphenamin, it is only about 3 to 4 times more spirocheticidal (0.003 gm. per kilo), so that its chemotherapeutic index of 5 is from two to four times less than that of arsphenamin.

Toxicity and Spirocheticidal Activity of Neoarsphenamin (Neosalvarsan) in Experimental Syphilis.—Kolle found the minimal curative dose of *neoarsphenamin* in rabbit syphilis to be about 0.015 gm. per kilogram. In my experiments the maximum tolerated dose of American-made neoarsphenamin (neosalvarsan) for rabbits has been about 0.350 gm. per kilo; the minimal curative doses have varied from 0.008 to 0.020 gm. per kilo and yielding, therefore, chemotherapeutic indices of 15 to as high as 40. These results are of considerable significance, for they indicate a greater range between toxic and curative doses than is observed with arsphenamin, as has been found true likewise in experimental trypanosomiasis.

Sodium arsphenamin (sodium salvarsan), which for a time enjoyed a brief popularity in the treatment of human syphilis, is borne by rabbits in about 0.210 gm. per kilo by intravenous injection. The minimal curative dose is about 0.020 gm. per kilo, yielding a chemotherapeutic index of about 10, which is about equal to that of arsphenamin but distinctly less than that of neoarsphenamin.

Toxicity and Spirocheticidal Activity of Silver and Other Arsphenamins in Experimental Syphilis.—Within the past few years Kolle has produced a *silver arsphenamin* (*silver salvarsan*) which he regards as having a higher curative activity than arsphenamin. In his experiments the average minimal curative dose has been about 0.004 gm. per kilo as compared with 0.010 gm. of arsphenamin. In my experiments the maximum tolerated dose of American-made silver arsphenamin for rabbits has varied from 0.090 to 0.110 gm. per kilo and the minimal curative doses from 0.004 to 0.010 gm. Some lots of silver arsphenamin are, therefore, more spirocheticidal than arsphenamin and when the toxicity is low the chemotherapeutic index may be somewhat higher (11 to 27) than the index for arsphenamin (10 to 20). It is to be noted, however, that the index for silver arsphenamin is not higher than the average index of neoarsphenamin (neosalvarsan) of American manufacture (15 to 40).

Kolle also found that *copper*, *gold* and *platinum arsphenamins* were more spirocheticidal (0.004 to 0.005 gm. per kilo) than arsphenamin (0.010 gm. per kilo), but usually slightly less spirocheticidal (0.004 gm. per kilo) than silver salvarsan; the former compounds have not been employed in the treatment of human syphilis. Danysz has prepared a compound of arsphenamin with antimony and silver designated as "*luargol*" or No. 102; according to Bonard,[22] it was found by Danysz to be borne by rabbits in dose of about 0.200 gm. per kilo with a minimal curative dose as low as 0.003 gm. per kilo and yielding, therefore, a chemotherapeutic index as high as 60. The one sample of this compound which I was able to test was borne by rabbits in dose of about 0.140 gm. per kilo, with a minimal curative dose of 0.016 gm., yielding an index of about 9. I believe that the differences in our results are largely due to the fact that the smaller dose employed by Danysz may be sufficient for sterilizing the testicular lesions but that much more is required to effect complete sterilization of the lymphatic glands.

Toxicity and Spirocheticidal Activity of Sulpharsphenamin in Experimental Syphilis.—Recently Voegtlin, Johnson and Dyer[23] described the preparation, chemical and biological properties of *sulpharsphenamin*, which may be injected subcutaneously as well as intravenously. The maximum tolerated

dose for rats has been reported by them as 0.400 to 0.500 per kilo, but the toxicity for rabbits has not been stated. The minimal curative dose for rabbits has been given as 0.015 gm. per kilo, although it is not clear in their paper whether or not this amount served to sterilize the lymphatic glands as well as the testicular lesions. In my experiments the maximum tolerated dose of sulpharsphenamin for rabbits by intravenous injection was about 0.300 gm. per kilo and the minimal curative dose, including sterilization of the lymphatic glands, about 0.022 gm. per kilo, yielding a chemotherapeutic index of about 14. By subcutaneous injection the maximum tolerated dose was about the same; the minimal curative dose was the same or slightly less, being from 0.018 to 0.024 gm. per kilo. This substance possesses, therefore, a chemotherapeutic index equal to or higher than that of arsphenamin, and equal to some lots of neoarsphenamin. A distinct advantage is the possibility of administering the compound to some human subjects by subcutaneous or intramuscular injection in the treatment of syphilis.

Toxicity and Spirocheticidal Activity of Sodium Cacodylate, Tryparsamid and Other Pentavalent Organic Arsenical Compounds.—With the exception of sodium arsanilate (atoxyl), all of the organic arsenical compounds discussed above are trivalent organic compounds of arsenic. The pentavalent compounds are much less curative for rabbit syphilis, just as the majority of them are distinctly less curative for experimental relapsing fever and trypanosomiasis.

Sodium cacodylate, which at one time had considerable popularity in the treatment of syphilis, has been found by Nichols[24] without curative activity in rabbit syphilis, even in amounts as large as the maximum tolerated dose. Runnels[25] found that the compound was borne by half-grown rabbits in dose of about 0.3 gm. per kilogram of weight; according to Nichols the maximum tolerated dose by intravenous injection is from 0.150 to 0.200 gm. per kilo.

Neisser[26] treated 19 monkeys with subcutaneous injections of doses of about 0.8 gm. per kilogram several days after inoculation with virus; 15 developed syphilis. Eighteen additional animals were treated with doses as high as 1.0 gm. per kilogram after the development of lesions, but none were cured. Neisser concludes his account by quoting Ehrlich who said, "The preparation is indeed non-toxic, but it is also therapeutically worthless."

Nichols[27] also found that *disodium ethyl arsonate* ("mon arsone") was without appreciable spirocheticidal activity in rabbit syphilis in amounts as large as the maximum tolerated dose by single intravenous injection.

Tryparsamid, which possesses a well-marked degree of trypanocidal activity, was found by Brown and Pearce[28] and myself to have a low spirocheticidal value. This substance is remarkably low in toxicity, being borne by rabbits in doses as high as 1.0 gm. per kilo, but the minimal curative dose required for complete sterilization of the testicles and lymphatic glands is as high as 0.3 to 0.5 gm. per kilo with a chemotherapeutic index as low, therefore, as 3.

Recently French investigators revived interest in the *phenyl arsonic acids* and especially in the sodium salt of amino-oxyphenyl arsonic acid ("189"). Levaditi and Martin[29] and Fourneau, Levaditi and their colleagues[30] have found this pentavalent compound borne by rabbits in doses as high as 0.250 gm. per kilo with a minimal curative dose of 0.100 to 0.150 gm. per kilo. Fourneau[31] states that the neurotropism of atoxyl may have been due to the presence of impurities and that the whole group of phenylarsonic acids are worthy of further study in the treatment of trypanosomiasis and spirochetosis.

Comparison of the Trypanocidal and Spirocheticidal Properties of Arsphenamin and Neoarsphenamin.—As stated in Chapter XII trypanocidal tests have proven of distinct value in evaluating the properties of different lots of arsphenamin and neoarsphenamin for the treatment of human syphilis. Not all trypanocidal arsenical compounds, however, possess corresponding spirocheticidal properties; some, like tryparasamid, are much more trypanocidal than spirocheticidal and others are more spirocheticidal than trypanocidal.

Comparative tests with different lots of arsphenamin and neoarsphenamin have shown, however, that the relation between trypanocidal and spirocheticidal properties is only broad and general as shown in Table 4.

TABLE 4.—A COMPARISON OF THE TRYPANOCIDAL AND SPIROCHETICIDAL PROPERTIES OF ARSPHENAMIN AND NEOARSPHENAMIN

COMPOUND	TRYPANOCIDAL TESTS (RATS)			SPIROCHETICIDAL TESTS (RABBITS)		
	MAXIMUM TOLERATED DOSE	MINIMAL CURATIVE DOSE	INDEX	MAXIMUM TOLERATED DOSE	MINIMAL CURATIVE DOSE	INDEX
Arsphenamin (A)	0.100	0.004	1:25	0.090	0.012	1:8
Arsphenamin (B)	0.140	0.008	1:17	0.120	0.006	1:20
Arsphenamin (C)	0.140	0.003	1:46	0.110	0.006	1:18
Silver arsphenamin	0.130	0.002	1:65	0.115	0.006	1:19
Neoarsphenamin (A)	0.260	0.006	1:43	0.250	0.008	1:31
Neoarsphenamin (B)	0.250	0.006	1:41	0.250	0.010	1:25
Neoarsphenamin (C)	0.260	0.006	1:43	0.240	0.010	1:24
Neoarsphenamin (D)	0.200	0.008	1:25	0.180	0.008	1:22
Neoarsphenamin (E)	0.250	0.002	1:125	0.250	0.012	1:21
Neoarsphenamin (F)	0.230	0.010	1:23	0.200	0.012	1:17

The toxicity of each compound was determined by intravenous injection into rats and rabbits, the table showing the maximum tolerated amounts per kilo of body weight. The trypanocidal tests were conducted according to my method with rats infected with *Tr. equiperdum* and the table shows the smallest amounts per kilo effecting complete sterilization. The spirocheticidal tests were conducted with rabbits infected intratesticularly with *Sp. pallida*, treatment being given 3 to 4 weeks later; the tables show the smallest amounts required for complete sterilization not only of the testicles but of the inguinal lymph-glands as well. In this connection it should be stated that these tests were conducted with compounds prepared by one laboratory during 1922 and at a time when their trypanocidal properties were particularly good.

Insofar as the toxicity of arsphenamin and neoarsphenamin is concerned, there is a fairly definite relation between the maximum tolerated doses of both compounds for the rat and rabbit. Sometimes the maximum tolerated dose for the rabbit is slightly less than that for the rat, but the differences are not great.

In every instance the chemotherapeutic index of trypanocidal activity was higher than the index of spirocheticidal activity; in other words arsphenamin and neoarsphenamin are more trypanocidal than spirocheticidal.

The relation between trypanocidal activity in the rat and spirocheticidal activity in the rabbit is not, however, definite or constant. Of course, it is

to be remembered in this connection that, while the trypanocidal activity of a compound can be determined within sharply defined limits, it is not readily possible to accomplish this in spirocheticidal tests. In a broad and general way the minimal spirocheticidal dose of arsphenamin (0.008 gm. per kilo) is from 2 to 3 times more than the minimal trypanocidal dose (0.003 gm. per kilo). The same is true of neoarsphenamin, since the spirocheticidal dose (0.012 gm. per kilo) is from 2 to 3 times more than the trypanocidal dose (0.006 gm. per kilo). Individual exceptions, however, are not lacking, a striking example being afforded by neoarsphenamin (E) in Table 4, which was trypanocidal in dose of but 0.002 gm. per kilo, but spirocheticidal only in amounts as high as 0.012 gm. per kilo.

Arsenical Compounds in the Treatment of Venereal Spirochetosis of Rabbits.—As described in Chapter XXI, several European and American investigators have described a disease of the penis and vulva of rabbits caused by *Sp. cuniculi* (Noguchi). According to Levaditi, Marie and Isaien[32] the spirochete is not infectious for man.

According to Noguchi,[33] the intravenous injection of arsphenamin in dose of 0.02 gm. per kilogram of body weight, resulted in the destruction of the spirochetes in the lesions in twenty-four hours. The lesions healed promptly and completely in seven days, and no recurrence was observed during a period of five months.

Kolle and Ruffer[34] found that it required the intravenous injection of 0.005 to 0.007 gm. silver arsphenamin to cure the lesions while 0.004 gm. per kilo was sufficient for the cure of the primary *Sp. pallida* lesions. In rabbits infected with both *Sp. pallida* and *Sp. cuniculi*, a dosage of silver arsphenamin of 0.004, 0.005 or 0.006 gm. per kilo body weight caused *Sp. pallida* to disappear and the chancre to heal, while the *Sp. cuniculi* still persisted in flat erosions. By this chemotherapeutic test they have furnished an additional method for the differentiation of the spirochetes and lesions.

Arsenical Compounds in the Chemotherapy of Experimental Yaws (Frambesia Tropica).—Experimental yaws of the rabbit is apparently more easily cured by spirocheticidal agents than experimental syphilis. As stated in Chapter XXI, the disease can be produced in rabbits by inoculation of the testicles with material from human cases of yaws or from experimentally produced lesions of monkeys or rabbits. Apparently *Sp. pertenuis* is not as virulent as *Sp. pallida* for rabbits; the spirochetes do not appear to be as widely distributed and there is a greater tendency for the development of immunity and spontaneous recovery. For these reasons the disease is more readily influenced by drugs and responds more promptly to arsphenamin and neoarsphenamin than the testicular and scrotal lesions of syphilis.

Nichols[35] was apparently first to discover the curative effects of arsphenamin in yaws of the rabbit. The intravenous injection of 0.0045 gm. per kilogram of body weight resulted in the permanent cure of four rabbits with well-developed testicular lesions, while, out of 5 rabbits infected with *Sp. pallida* and treated with a similar dose, 3 relapsed in 31, 36 and 49 days respectively. Castelli[36] subsequently confirmed the high curative activity of salvarsan and neosalvarsan in testicular and scrotal yaws of the rabbit, finding that the latter in doses of 0.015 to 0.035 gm. per kilogram by intravenous injection served for the sterilization of these local lesions in 3 to 6 days. Schamberg and Klauder[37] failed to cure the scrotal lesions of yaws in rabbits with 0.005 gm. of arsphenamin per kilo, but observed that the curative dose of neoarsphenamin was 0.008 gm. per kilo. No one, however, has yet reported upon the presence of *Sp. pertenuis* in the lymph-glands of rabbits; it is highly probable that in experimental yaws the spirochetes gain access to these tissues, just as *Sp. pallida* does in experimental syphilis, and if so, the amounts of salvarsan and neosalvarsan required for complete sterilization would be larger than reported above for the healing of the testicular, scrotal or other external lesions with disappearance of spirochetes.

An abundance of clinical data shows that the curative properties of arsphenamin and neoarsphenamin are even more striking in dissipating the external lesions of yaws in human beings than the lesions of syphilis; but I shall discuss this subject in more detail in a later chapter.

Mechanism of Spirocheticidal Activity of Arsenical Compounds.—Soon after the discovery of the trypanocidal and spirocheticidal (for *Sp. gallinarum*) properties of atoxyl, the mechanism of its action in living animals commanded considerable investigation. In 1907, Uhlenhuth and Gross[38] thought that atoxyl inhibited the multiplication of *Sp. gallinarum* and brought about their destruction by stimulating the antibody producing tissues and particularly by facilitating phagocytosis. Similar views were expressed by Aoki,[39] in 1914, investigating the influence of atoxyl upon antibody production in hen spirillosis.

Levaditi and McIntosh[40] and later Levaditi and Yamanouchi,[41] noting that atoxyl was practically without toxicity for *Sp. gallinarum in vitro* but curative *in vivo*, advanced the theory that the compound first underwent a change *in vivo*, in which the liver was intimately involved, with the production of spirocheticidal substances. The mechanism was regarded the same as occurring in the cure of trypanosome infections; according to Levaditi[42] atoxyl is reduced primarily in the liver and this product then unites with its proteins to form "trypanotoxyl," the active trypanocidal agent. Gonder,[43] working in Ehrlich's laboratory, then showed that while solutions of salvarsan *in vitro* were able to reduce the motility of *Sp. gallinarum* and various trypanosomes, infectivity was not destroyed. However, if salvarsan was administered to fowls and a little later blood drawn, the serum secured and mixed with blood containing *Sp. gallinarum in vitro*, the injection of such mixtures in rice birds was not followed by infection, suggesting that some change had occurred in the serum with the production of more active spirocheticidal compounds. Recently, Lee[44] advanced a somewhat similar hypothesis regarding the mechanism of the spirocheticidal activity of arsphenamin and neoarsphenamin in syphilis by stating that these medicaments united with the proteins of cells about the foci of infection and that these cellular-protein-arsphenamin compounds were the active spirocheticidal substances.

Ehrlich has long maintained that atoxyl was reduced in the animal to an active trivalent compound and that the latter explained why atoxyl was active *in vivo* and not *in vitro*. Ehrlich believed that the power of reducing arsenical compounds varied in animals of different species, but was more or less constant for the animals of any one species and that this explained the varying effects of atoxyl in animals of different species analogous to the different oxidizing activities of different microörganisms.

Continuing this line of thought, Ehrlich and Bertheim showed that the oxidation of salvarsan *in vitro*, with the formation of "arsenoxid," increased toxicity 7 to 10 times for mice and rabbits, and at the same time increased trypanocidal and spirocheticidal activity. Ehrlich believed that the same process occurred in man and the lower animals and that these oxidation products constituted the active spirocheticidal substances. According to Ehrlich, the pentavalent compounds first require reduction to the more parasitropic trivalent substances and the increase of spirocheticidal activity of atoxyl in an emulsion of liver cells noted by Levaditi was due to a reduction *in vitro*. According to Friedberger, a similar reduction of atoxyl can be brought about by thioglycol acid which Bertheim explains by the primary production of "arsenoxid" followed by union with the thioglycol acid and the production of *p*-amino-phenyl-arsenthioglycol acid.

I have previously discussed in more detail the mechanism of trypanocidal activity of pentavalent and trivalent organic compounds of arsenic, calling attention to the work of Voegtlin and Smith indicating that arsphenamin and neoarsphenamin are probably not trypanocidal as such, but first require oxidation either *in vitro* or *in vivo*. While similar experiments have not been conducted with *Sp. pallida*, I think it is permissible to explain the spirocheticidal activity of these substances on the same basis. The weight of experimental data strongly supports the hypothesis that the organic compounds of arsenic must first undergo the processes of oxidation or reduction, according to the nature of the compound, before toxicity for parasites is obtained. In this connection I may mention however, that Schumacher[45] has recently advanced the hypothesis that the arsenobenzols destroy spirochetes and other organs by abstracting oxygen from them. His experiments were not conducted with *Sp. pallida* but by histo-chemical studies with other organisms and cells to show these effects.

As will be discussed immediately, there is evidence to support the theory that the curative activity of arsphenamin and neoarsphenamin in syphilis may be aided by antibody production when the drugs are repeatedly given. But cures effected by single large doses are probably due entirely to the "oxids," since there is no time for antibody production; but just how these "oxids" bring about the destruction of *Sp. pallida* and other spirochetes and trypanosomes is not known. Apparently these substances unite with the protoplasm by means of sulphydril compounds. Probably the primary effect is an actual increase in the numbers and activity of the attacked parasites, as indicated by the investigation of Frei,[46] followed by protoplasmic changes and death.

Furthermore, as shown by Voegtlin and Thompson,[47] the rate of excretion of the arsenical compound has an important influence upon its parasiticidal activity, the directly toxic trivalent oxid compounds showing the slowest rate, the pentavalent arsenicals the fastest, and the arsenobenzene compounds occupying an intermediate position. Apparently changes in chemical constitution affect the physical properties of these compounds, which in turn determine the rate of diffusion and distribution in the body and the path and rate of excretion of arsenic, thus governing the toxicity for the host and the parasiticidal effects.

Influence of Arsenical Compounds upon Antibody-production in Syphilis. As previously mentioned, one of the oldest theories explaining the curative activity of arsenical compounds supposes that they stimulate the body cells to produce antibodies effecting the destruction of spirochetes. The primary and most important action of these drugs is direct destruction of the parasites, because their action *in vivo* is too rapid for antibody-production in the cure of acute infections with single doses; but since trypan-red and other dyes, as well as organic arsenical compounds, are known to engender temporary immunity following the cure of trypanosomiasis of rats, it is entirely likely that in the treatment of syphilis and other spirochetic infections the repeated administration of the organic arsenical compounds aids in the production of immune substances engendered by antigenic substances from spirochetes after their destruction. As stated in Chapter XVII, my experiments have shown that arsenical and mercurial compounds do not increase antibody-production in rabbits immunized with vaccines of trypanosomes. A similar set of experiments with a vaccine of *Sp. pallida* have yielded like results of a negative character. Rabbits, immunized with *Sp. pallida* vaccine and treated with arsphenamin and neoarsphenamin did not produce agglutinins and alexo-fixagins for *Sp. pallida* any better than the untreated controls.

Insofar as experiments of this kind are concerned, I believe that the results are negative and have shown that arsphenamin and neoarsphenamin, administered to rabbits in amounts analogous to those employed in the treatment of human syphilis, possess no effect upon increasing the production of agglutinins and alexo-fixagins for dead spirochetes.

Naturally, negative results of this kind render improbable that the organic arsenical compounds aid in the production of immunity in syphilis; but are the results directly applicable to syphilis? It is well known that the only resistance or immunity developing in syphilis is due to the presence of living spirochetes in the tissues. Are arsphenamin, neoarsphenamin and other organic arsenical compounds able to aid immunological processes in the presence of living spirochetes, even though they have no influence of this kind with dead spirochetes?

I have no data to offer in answer to this question, because it is difficult to measure resistance or immunity in experimental syphilis and the value of *in vitro* tests is sharply limited. But I believe that, in the treatment of syphilis after each injection of arsphenamin, neoarsphenamin or other active organic arsenical compound, there is a destruction of some spirochetes within the following twenty-four to forty-eight hours by the therapeutically active oxidation or reduction products, followed by the development of some immunity principles engendered by the antigenic substances released from the destroyed spirochetes; and that these immune substances at least aid in holding the activity of spirochetes in check or latency, if they are not actually destructive for them.

Acquired Resistance of Spirochetes to Arsphenamin and Neoarsphenamin.—As stated in Chapter XII, trypanosomes are readily rendered resistant to atoxyl, arsacetin, arsphenamin and other arsenical compounds by treating mice with subcurative amounts or inoculating rats previously treated with the compound. Of far greater practical importance is the question whether or not *Sp. pallida* can be rendered resistant, in the same manner, to arsphenamin, neoarsphenamin and other organic arsenical compounds employed in the treatment of syphilis.

Akatsu and Noguchi[48] were able to increase the *in vitro* resistance of *Sp. pallida*, *Sp. microdentium* and *Sp. refringens* from three to five and one half times their natural resistance to salvarsan and neosalvarsan within a period of 3 to 4 months embracing 6 to 10 transfers. This work was conducted by planting cultures of the spirochetes in 5 c.c. of Noguchi's ascites-kidney-broth medium (not in the agar medium) containing arsphenamin or neoarsphenamin. Preliminary experiments showed that about 0.375 c.c. of a 1:10,000 alkalinized solution of arsphenamin in water added to 5 c.c. of the culture medium would suppress the growth of *Sp. pallida*, but by beginning with smaller amounts and transferring the culture every two weeks to fresh medium containing progressively more arsphenamin, it was found after six to eight transfers that 0.8 c.c. of the solution was not inhibitory. Neosalvarsan was inhibitory at first in dose of 0.5 c.c. of 1:10,000, but after a similar number of such transfers it produced a resistance up to 1.2 c.c. of 1:10,000 solution. Similar resistance was acquired by *Sp. microdentium* and to a lesser extent by *Sp. refringens*. This resistance gradually disappeared when the spirochetes were cultivated in drug-free media for several generations; it is entirely likely, however, that the resistance engendered *in vivo* persists much longer. In acquired resistance of trypanosomes *in vivo* to arsenical compounds, the condition persists for long periods of time.

Klauder[49] has recently shown that resistance of *Sp. pallida* to arsphenamin and neoarsphenamin may be acquired *in vivo* and his results are naturally of great interest and importance in the treatment of syphilis. Klauder found that the minimal curative dose of arsphenamin for rabbits with testicular lesions was about 0.010 gm. per kilogram by intravenous injection. By treating rabbits with subcurative doses and transplanting to fresh rabbits in much the same manner as these tests are conducted with trypanosomes, it was found that after several transfers the resistance acquired was of such degree that the minimal curative dose was more than 0.016 gm. per kilogram of weight. Fantl[50] has reported that the spirochetes disappear less rapidly from lesions of patients who had previously received mercury than from those of untreated cases, and concluded that the

organisms acquired a resistance to arsphenamin as a result of the mercurial treatment. According to his experiments, spirochetes derived from mercury-treated patients (mercuric chlorid and salicylate intramuscularly) remained motile in dark-field preparations in the presence of 0.01 per cent. arsphenamin added to the serum, for only a short time, whereas spirochetes from untreated cases remained motile for hours under the same conditions. Owing to the fact that group resistance of trypanosomes is confined only to compounds bearing chemical relationship, I am inclined to accept these results with much reserve; if mercury does engender a resistance of *Sp. pallida* to arsphenamin, it probably is of but short duration and minor degree.

These experiments show, therefore, that contrary to previous opinion, spirochetes can be rendered resistant to arsphenamin and neoarsphenamin *in vitro* and *in vivo*. My impression is, however, that resistance of *Sp. pallida* is not engenered nearly as rapidly as resistance of the trypanosomes and particularly *Tr. equiperdum*.

CHAPTER XXIV

TOXICITY AND SPIROCHETICIDAL PROPERTIES OF MERCURIAL COMPOUNDS

A great deal of interest is attached to the possible spirocheticidal activity of compounds of mercury in view of the fact that mercury has been employed for centuries in the treatment of syphilis. An abundance of clinical experience and data shows that mercury possesses curative activity in human syphilis; in frambesia or yaws, however, it has been less efficacious.

In experimental spirochetic infections, mercurial compounds have been found much less curative than the trivalent organic arsenical compounds. One reason for this is the higher toxicity of the former preventing the administration of sufficiently large amounts. *Magna therapie sterilisans* is easily possible in many experimental spirochetic infections with single doses of several of the organic arsenical compounds; it is hardly possible, however, with a single dose of any of the mercurial compounds unless the maximum tolerated or even toxic amounts are given. Aside from this question of organotropism and dosage, mercury is less parasitropic than arsphenamin and other arsenical compounds of this group.

Toxicity and Spirocheticidal Activity of Mercurial Compounds in Relapsing Fever and Fowl Spirillosis.—In *relapsing fever* of rats (*Sp. novyi*), Schamberg, Raiziss and myself[1] found mercuric chlorid, mercury salicylate and benzoate of mercury absolutely ineffective even in amounts as high as the maximum tolerated doses administered by intravenous injection (0.003–0.004 gm. per kilo) within two hours after infection. Of a series of new mercury-naphthol compounds two possessed slight spirocheticidal properties inasmuch as the infection was restrained by them for two to six days. In no instance, however, have we found a mercurial compound capable of effecting complete sterilization.

In experimental *fowl spirillosis*, Uhlenhuth and Manteufel[2] found that a combination of atoxyl and mercury (*mercury arsanilate*) was effective in doses one third to one fifth less than the maximum tolerated amounts. A preparation of colloidal mercury, mercury salicylate and acetylmercury arsanilate were also slightly effective in the maximum tolerated doses, but *Sp. gallinarum* infections are so easily influenced that similar results cannot be obtained in other spirochetic infections. Hahn and Kostenbader[3] found a fluorescin compound of mercury curative in dose of 0.008 gm. per kilogram (maximum tolerated dose 0.018 gm.) and benzolsulphuric acid azomercury salicylic acid slightly curative. Gruhzit[3a] found that *Spirochaeta novyi* in rats is strongly resistant to mercurial medication. The lethal dose of mercuric iodid or acetate was not able to free the animals from spirochetes. Mercurosal when administered before inoculation of rats and followed with daily administrations of three fourths of a minimum lethal dose shortened the life of *Spirochaeta novyi* from five days to three days.

Toxicity and Spirocheticidal Activity of Mercurial Compounds in Experimental Syphilis and Yaws.—In experimental *syphilis* and *yaws*, Nichols[4] found that the intravenous injection of *mercuric chlorid* was practically without effect upon the spirochetes in well developed testicular lesions when given in dose of 0.001 gm. per kilo by intravenous injection. Nichols found this amount to be about the maximum tolerated dose for rabbits although in my experiments the tolerated dose was from 0.002 to 0.003 gm. per kilogram. Nichols found that mercuric chlorid in dose of 0.003 gm. per kilogram of weight had some curative effect in both syphilis and yaws as shown by the disappearance of the spirochetes and healing of the testicular lesions; his rabbits died of nephritis, however, before the final results could be observed. I have had similar results with mercuric chlorid and *mercurophen* and believe that both of these compounds in dose of 0.002 to 0.004 gm. per kilogram (the maximum tolerated doses) can bring about sterilization of the testicular lesions but not usually of the lymphatic glands. Nichols has observed similar results with *mercuric salicylate* (dissolved in a solution of potassium carbonate) and I believe it can be stated that the chemotherapeutic index for these compounds in both rabbit syphilis and yaws is about 1, that is, they are just about curative in the maximum tolerated doses.

Neisser[5] injected 15 monkeys with *mercury salicylate* in dose of 0.052 to 0.120 gm. per animal just before inoculation with virus; 12 developed syphilis and 3 escaped. Of 21 animals injected with 0.050 to 0.080 gm. per animal at the time of inoculation, 15 developed syphilis and 6 did not. Of 13 animals injected with *mercuric chlorid* in dose of 0.030 to 0.035 gm. per animal at the time of inoculation, 9 developed syphilis and 4 escaped. Of 6 animals treated with 19 c.c. of a 0.5-per cent. solution of *colloidal mercury* by intravenous injection, 5 developed syphilis and 1 escaped.

Neisser treated 39 monkeys with *mercury salicylate* after the development of primary lesions; 11 were apparently cured and 22 were not. Of 15 monkeys treated with *mercuric chlorid* after the appearance of primary lesions, 5 were apparently cured and 10 were not. Of 10 monkeys treated with the colloidal mercury preparation, all were apparently cured.

Recently White, Hill, Moore and Young[6] have described a new mercurial compound, the disodium salt of hydroxymercurifluorescein, designated as "flumerin." This compound is a dark red powder with greenish iridescence and is easily soluble in water, 2-per cent. solutions being commonly employed. The compound contains about 32.5 per cent. mercury (theoretical content 33.8 per cent.), with the formula $C_{20}H_{10}O_6NA_2Hg$.

The single maximum tolerated dose for rabbits and dogs by intravenous injection is about 0.030 gm. per kilogram; in dose of 0.005 gm. per kilogram the animals can tolerate repeated doses, even as many as twenty at intervals of three to five days. Inasmuch as the compound contains 32.5 per cent. mercury it is remarkable from the standpoint of low toxicity; I know of no other compound comparable with it from this standpoint. In the treatment of rabbit syphilis single doses of 0.030 gm. per kilogram usually brought about complete sterilization not only of the testicular lesions but of the lymphatic glands as well; multiple doses of 0.005 gm. per kilogram were likewise curative. Flumerin, therefore, is one of the best spirocheticidal mercurial compound known today, but it is to be hoped that additional investigations will be made to evolve a mercurial compound with a higher chemotherapeutic index.

Gruhzit states that *mercurosal* in a single dose of 0.010 to 0.015 gm. per kilogram has cured syphilitic orchitis of rabbits as determined by lymph gland transfer. When administered at two or three day intervals in dose of

0.0033 gm. per kilogram, 70 per cent. of rabbits were cured. Eight doses of 0.0017 gm. per kilogram at intervals of two to five days did not render the lesions free from spirochetes. A dose of from 0.003 to 0.005 gm. per kilogram rendered the lesions free of spirochetes on an average of about three doses and produced no noticeable toxic symptoms in the animals.

Therefore, while mercurial compounds possess some spirocheticidal properties *in vivo*, their high toxicity usually prevents the administration of sufficient amounts to bring about well defined curative effects in single doses; repeated small doses are usually required. From the standpoint of reduced toxicity "flumerin" is an advance, but unfortunately the reduction in toxicity of this compound for the test animal (organotropism) is accompanied by a similar reduction in toxicity for *Sp. pallida* (curative activity or parasitropism) so that the ratio between the two (the chemotherapeutic index) is but slightly better than observed with mercuric chlorid and mercurophen.

Mechanism of Spirocheticidal Activity of Mercurial Compounds.—Practically nothing is known of the mechanism of the spirocheticidal activity of mercurial compounds. They possess an extremely high toxicity for most spirochetes *in vitro*, but the effects *in vivo* are much less powerful. Single doses equal to the sublethal or maximum tolerated amounts are almost without effect in experimental relapsing fever and syphilis although sometimes curative in fowl spirillosis.

It is commonly stated that these results are due to the toxicity of most mercurial compounds which prevents the administration of curative doses. But this is not exactly true. For example, mercuric chlorid can be administered to rabbits by intravenous injection in doses of 0.003 gm. per kilogram giving a dilution in the blood probably not higher than 1:20,000 but this dose has little or no effect upon testicular lesions of syphilis whereas a similar dose of arsphenamin exerts distinctly curative effects.

Furthermore, according to White, Hill, Moore and Young, "flumerin," which contains about 32.5 per cent. of mercury, must be injected intravenously in the maximum tolerated dose of 0.030 gm. per kilogram before curative effects are found in rabbit syphilis. This dose is about three times larger than the minimal curative dose of arsphenamin.

I mention these facts to show that while mercurial compounds are more spirocheticidal *in vitro* than arsphenamin and neoarsphenamin, they are many times less spirocheticidal *in vivo* even when given and tolerated in fairly large doses. That mercury possesses curative activity in human and experimental syphilis cannot be disputed; an abundance of clinical data collected during the past 400 years is ample proof of this fact in human syphilis. But it is highly probable that mercury as administered does not reach or act upon the spirochetes direct, but first requires a process of dissociation with or without the production of new compounds, like union with blood or cellular proteins with the formation of albuminates which are less spirocheticidal than the unchanged compounds. Bergel[7] has recently advanced the theory that mercury is not directly spirocheticidal but acts upon the lymphocytes of the syphilitic exudate releasing from these a lipolytic ferment which is capable of bringing about the gradual destruction of the organisms. While there is little or no direct evidence to support these theories, it is hoped that further researches will yield more information on the exact mechanism of the spirocheticidal activity of not only mercury, but also of bismuth, vanadium, thorium, iodin and other substances as well.

Effect of Mercuric Chlorid upon Antibody-production in Syphilis.—Furthermore there is little direct evidence to support the theory that mercury cures syphilis by increasing the production of antibodies destructive for *Sp. pallida*.

To the best of my knowledge no one has actually demonstrated in a conclusive manner an increase of agglutinins, opsonins or spirocheticidal antibodies in syphilitics attributable to the effects of medicaments including mercurial compounds. It must be admitted, however, that such a possibility exists even though the immunity cannot be measured by *in vitro* tests. We know that certain of the dyes acting on *Sp. novyi* appear to release antigenic substances tending to engender a higher degree of immunity than develops in untreated infections. The phenomenon is even much more apparent in the cure of trypanosomiasis by single doses of trypanocidal dyes, organic arsenical and organic antimonyl compounds. Is a similar phenomenon operative in syphilis treated with mercurial compounds?

My experiments with *Sp. pallida* vaccines have yielded negative results. Rabbits immunized with weekly intravenous injections of a vaccine of culture *Sp. pallida*, accompanied by the injection of 0.0005 gm. of mercuric chlorid per kilogram of weight about 4 hours after each injection of vaccine, have not shown any greater degree of production of agglutinins and alexofixagins (complement-fixing antibodies) than control rabbits receiving the vaccine alone. Several investigators including Toyama and myself, have found that mercury may slightly influence (depress or increase) antibody production for bacteria, but these results cannot be applied to syphilis and the experiments with *Sp. pallida* vaccines have been negative.

But can these results be applied to the effect of mercury upon living spirochetes? As discussed in Chapter XVII the immunity engendered by drugs acting on living trypanosomes is greater than that upon dead trypanosomes. We know that immunity or resistance in syphilis is dependent upon the presence of living spirochetes in the tissues. I have no experimental evidence to show that mercury acting upon living *Sp. pallida* releases antigenic substances capable of engendering a degree of immunity, but I believe such may occur in the treatment of syphilis.

Acquired Resistance of Spirochetes to Mercury.—Is *Sp. pallida* susceptible of acquiring resistance to mercurial compounds? This is a question of fundamental importance in the treatment of syphilis and there is very little data available upon which to express an opinion.

Akatsu and Noguchi[8] have found that the addition of 0.02 c.c. of 1:1000 mercuric chlorid solution to 5 c.c. of ascites-broth effectually inhibited the growth of cultures of *Sp. pallida, Sp. microdentium* and *Sp. refringens*. By starting with smaller amounts and gradually increasing with subcultures every two weeks they were able to raise the resistance of *Sp. pallida* until more than 0.5 c.c. of the 1:1000 bichlorid solution was required within ten weeks, an increase of 25 times the original amount. The resistance of *Sp. microdentium* was raised 10 times and that of *Sp. refringens* 30 times the original dose by this *in vitro* method. This acquired resistance gradually disappeared when the spirochetes were cultivated again in drug-free media for several generations.

Fantl[9] reports that the motility of spirochetes taken from the lesions of persons previously treated with mercuric chlorid or salicylate by intramuscular injection, are more resistant to the effects of mercuric chlorid added to dark field preparations in 0.2 per cent. than the spirochetes from untreated cases.

It is very much hoped that someone will determine if the resistance of *Sp. pallida* to mercurial compounds can be engendered in rabbit syphilis and if so, whether there is a coincident increase of resistance to arsphenamin and neoarsphenamin. I predict, in view of the results observed by Akatsu and Noguchi, that *Sp. pallida* could be rendered resistant in this way but that there would be no, or but slight and temporary, coincident resistance to arsphenamin and neoarsphenamin.

CHAPTER XXV

TOXICITY AND SPIROCHETICIDAL PROPERTIES OF BISMUTH COMPOUNDS

At the present time bismuth compounds and particularly the tartrobismuthates are commanding considerable attention in the treatment of syphilis and are being especially employed by French syphilologists; indeed, a rather large literature has already accumulated, since Sazerac and Levaditi in 1921 recommended the intramuscular administration of sodium and potassium tartrobismuthate in the treatment of this disease.

The spirocheticidal properties of several organic and inorganic compounds of bismuth, as well as of the metal itself, have been determined in experimental infections of the lower animals which are briefly summarized in this chapter. The curative properties in human syphilis have likewise been extensively reported upon although it is still too early to express a final opinion of the value of bismuth in the treatment of syphilis. In this chapter, I shall briefly review the results of these observations, reserving for Chapter LV a more complete discussion of their toxicity for the lower animals and human beings and for Chapter LXVI, a discussion of their curative properties in the different forms of human syphilis as compared with mercury and the organic arsenical compounds.

Toxicity and Spirocheticidal Properties of Bismuth in Fowl Spirillosis.—The toxicity of bismuth was first investigated experimentally by Balzer[1] in 1899 to determine if it could be used in the treatment of syphilis. Bismuth citrate was chiefly employed but the investigation was abandoned when he found that severe reactions were produced in dogs, especially stomatitis and enteritis. In 1916 Robert and Sauton[2] published the results of a study of the curative activity of sodium tartrobismuthate prepared according to the method of Cowley[3] in experimental fowl spirillosis (*Sp. gallinarum*), which has since stimulated a great deal of laboratory and clinical investigation with bismuth compounds in the treatment of experimental syphilis. These investigators found that *in vitro* a 1:100 solution of sodium tartrobismuthate quickly destroyed the motility of *Sp. gallinarum* in fowl blood.

Toxicity tests showed that the maximum tolerated dose by intravenous injection into normal fowls was 0.030 to 0.035 gm. per kilogram of weight and 0.015 to 0.020 gm. for infected fowls. By intramuscular injection the tolerated dose for healthy animals was found to be 0.100 gm. per kilogram.

When fowls were injected intravenously with a dose of 0.020 to 0.030 gm. per kilogram, or intramuscularly with a dose of 0.050 to 0.070 gm. per kilogram, about four hours before infection with *Sp. gallinarum*, the infection was usually retarded, but complete prevention did not usually occur. Doses of 0.005 to 0.015 gm. per kilogram intravenously and 0.060 to 0.070 gm. intramuscularly, injected six hours after infection, invariably cured the animals. The intravenous injection of 0.015 gm. per kilogram twenty-four hours after infection sometimes proved curative, but seldom or never when given forty-eight and seventy-two hours after infection. Two doses of 0.010 gm. each per kilogram however, generally cured infections of forty-eight and seventy-two hours' duration. They concluded that the tartrobismuthate of sodium, contrary to action *in vitro*, exercises a spirocheticidal action on the *Sp. gallinarum* in the animal. Further work was interrupted at this time by the World War and the death of Sauton.

Toxicity and Spirocheticidal Activity of Bismuth in Rabbit Syphilis.—In 1921, Sazerac and Levaditi[4] and Levaditi and Sazerac[5] conducted extensive experiments with various compounds of bismuth in the prevention and treatment of rabbit spyhilis which have resulted in establishing the value of bismuth in the treatment of human syphilis.

Sazerac and Levaditi infected rabbits with different strains of *Sp. pallida* —their so-called dermotropic and neurotropic strains described in Chapter XXXVI, and after the development of testicular lesions administered the compounds by intramuscular or intravenous injection. As a general rule, the results were evaluated according to the rate of disappearance of spirochetes and healing of the testicular lesions; they do not appear to have removed the lymphatic glands for inoculation to determine if sterilization was complete.

The intramuscular injections of precipitated bismuth (prepared by the reduction of sodium tartrobismuthate), sodium and potassium tartrobismuthate, bismuth oxyiodgallate, bismuthogallate, bismuth lactate and bismuth ammonium lactate, were curative in doses of 0.025 to 0.100 gm. per kilogram of weight, insofar, at least, as to effect a disappearance of spirochetes from the testicular lesions with healing and no evidences of recurrence. The application of a powder of sodium and potassium tartrobismuthate or a 33-per cent. ointment to local lesions possessed prophylactic and curative properties similar to mercury under the same conditions.

Similar results were observed in the treatment of venereal spirochetosis of rabbits, the intramuscular administration of sodium and potassium tartrobismuthate in dose of 0.100 gm. per kilogram of weight, effecting a disappearance of *Sp. cuniculi* and healing of the lesions.

Klauder[6] found that the maximum tolerated dose of sodium and potassium tartrobismuthate in aqueous solution for rabbits by intravenous injection was 0.125 gm. per kilogram. With the oil suspension of the drug, animals survived doses up to 0.2 gm. per kilogram, but succumbed to injections of 0.25 gm. Animals injected with potassium tartrobismuthate survived doses up to 0.25 gm. per kilogram, but died following injections of 0.3 gm. The maximum tolerated dose of bismuth trioxid in olive oil was 0.4 gm. per kilogram. Therapeutic tests were conducted with syphilitic rabbits showing well developed testicular lesions containing numerous actively motile spirochetes. The amounts of the compounds per kilogram of weight required to effect a prompt disappearance of the spirochetes, healing of the lesions and no recurrence during a period of two months was of sodium and potassium tartrobismuthate in aqueous solution and in olive oil and potas-

sium tartrobismuthate in aqueous solution about 0.05 gm. per kilogram of body weight and 0.15 gm. per kilogram for bismuth trioxid.

Kolle[7] has observed that while intravenous injections of mercury and bismuth may not prove spirocheticidal, intramuscular injections are more efficacious in that the development of spirochetes and syphilitic lesions in rabbits may be inhibited. Bismuth deposited in the ears of rabbits for example, was found to prevent the development of scrotal and testicular lesions until the deposited drug was removed by excision, following which the lesions usually developed.

Recently Sazerac and Vaurs[8] have observed that intraperitoneal injections of insoluble bismuth compounds were efficacious in the treatment of *Tr. brucei* and *Spirochaeta cuniculi* infections and they suggest that phagocytes may either change the compounds and render them soluble or else transport the insoluble particles to the infected tissues, although there is an yet no direct evidence of the latter taking place.

Bismuth compounds and especially sodium and potassium tartrobismuthate possess, therefore, well-defined spirocheticidal activity in experimental syphilis. In a general way the single therapeutic dose is about five times smaller than the single maximum tolerated or toxic dose giving a chemotherapeutic index of 5. This index is, therefore, much higher than observed with the mercurial compounds and indeed, higher than observed with all compounds examined to the present time with the exception of the organic arsenical compounds. Milian[9] states that if the chemotherapeutic index of arsphenamin is stated as 10 (that is, the curative dose for rabbit syphilis is 10 times less than the toxic dose), the index for sodium and potassium tartrobismuthate may be stated as 7 and that of mercury at 4. The results of my experiments have been approximately the same for arsphenamin and bismuth but with an index of only 1 for mercurial compounds.

Mechanism of Spirocheticidal Activity of Bismuth Compounds.—Practically nothing is known of the exact mechanism of spirocheticidal activity of bismuth compounds *in vitro* and *in vivo*. In a few experiments, I have found the water soluble potassium and sodium tartrobismuthate spirocheticidal *in vitro* and capable of destroying motility of *Sp. pallida* in high dilutions as well as bringing about their complete destruction as determined by testicular inoculations in rabbits, but in both respects this bismuth compound was less active than mercuric chlorid and mercurophen.

It is highly probable that bismuth acts upon *Sp. pallida* in the tissues in much the same manner as mercury. It is likely that the element forms rather loose combination products with the proteins of the blood and cells which may reduce spirocheticidal activity since parasitropic activity *in vivo* is less than *in vitro*. Following the production of these bismuth albuminates which form *in vitro* much more slowly and less extensively than with mercuric chlorid, the bismuth becomes dissociated and it is highly probable that the bismuth ions are responsible for both the spirocheticidal and toxic effects. Levaditi believes that the bismuth enters a colloidal state and exerts direct spirocheticidal effects in this condition; a further discussion of this subject will be found in Chapter LIV.

Whether or not more complex compounds of essentially different chemical composition are produced *in vivo* similar to the oxidation product of the arsenobenzols and organic antimonyl compounds cannot be stated at the present time. The affinity of bismuth for body cells and parasites is less than exhibited by mercurial compounds but when sufficient amounts are administered the toxic effects upon both have several features in common with the mercurial compounds.

Whether or not bismuth compounds increase antibody production in syphilis cannot be stated at present. It is entirely likely, however, that their effects in this respect are similar to those of mercury. That is, bismuth does not stimulate the antibody producing tissues directly but liberates antigenic principles from spirochetes which hasten the stimulation of these tissues. This process is slow, however, and aids in the treatment and cure of syphilis with repeated doses of a bismuth preparation; in the destruction of spirochetes within the first day or two after administration, the effects of bismuth are direct upon the parasites as this action is too quick for the production of antibodies.

Acquired Resistance of Spirochetes to Bismuth.—It is not known at present whether or not spirochetes and especially *Sp. pallida* acquire increased resistance or fastness to bismuth *in vitro* and *in vivo*, as has been demonstrated with the mercurial compounds *in vitro* and with arsphenamin both *in vitro* and *in vivo*. It is entirely likely, however, that such could be accomplished. Clinical experience has shown that spirochetes resistant to mercury or the arsenobenzols are susceptible to bismuth and for this reason compounds of the latter are useful in the treatment of syphilis when it is suscepted that this resistance or fastness has been acquired in any case or when the body cells have developed an intolerance for arsenic or mercury.

CHAPTER XXVI

TOXICITY AND SPIROCHETICIDAL PROPERTIES OF THE IODIDS

Owing to the widespread use of potassium and sodium iodids in the treatment of syphilis and yaws, considerable interest is attached to the question of their spirocheticidal activity in experimental infections. Curiously, but little investigation has been devoted to this subject; apparently clinical views to the effect that the iodids in syphilis and yaws are beneficial and curative by aiding the removal of inflammatory tissue without direct destructive effects upon the spirochetes, has been generally accepted.

Toxicity and Spirochaeticidal Activity of the Iodids in Experimental Infections.—In 1910 Tomasczawski[1] stated that he was unable to detect any prophylactic or curative properties of *potassium iodid* in experimental syphilis of rabbits and monkeys, but in 1911 Neisser[2] reported that he was able to prevent and cure syphilis in monkeys by the subcutaneous injection of very large doses of potassium iodid. For example, he injected 7 monkeys with 3.6 to 3.95 gm., corresponding to about 120 gm. for an adult human being, seven

days after inoculation; three animals developed syphilis and four did not. To each of another series of animals he gave 8.25 gm. corresponding to about 210 gm. for the average adult human being, and all escaped infection. A third series received 5.5 gm. each and all developed primary lesions. In other words the dose of potassium iodid required for the prevention of the development of primary lesions in monkeys was from 7 to 8 gm. injected within seven days after inoculation. These doses are too large for administration to human beings, but the experiments show that potassium iodid possesses a slight degree of spirocheticidal activity.

Nichols,[3] in 1911, determined that the maximum tolerated dose of potassium iodid for rabbits by single intravenous injection was about 0.030 gm. per kilo. The intravenous injection of this amount to rabbits with well-developed testicular lesions of syphilis and yaws had no definite curative effects. One rabbit, however, treated with the intramuscular injection of potassium iodid in dose of 1.0 gm. per kilogram of weight, was apparently cured in 10 days; another receiving a subcutaneous injection of 0.5 gm. per kilogram was not benefitted over a period of 10 days and extensive necrosis developed at the site of injection.

Messerschmidt[4] has experimented with fowl spirillosis. Repeated doses of potassium iodid in amounts of 0.1 gm. per kilogram by oral and intramuscular administration had no appreciable preventive or curative effects. One compound designated as *sodium sozoiodid* was definitely curative when given in two doses of 0.1 gm. each per kilogram by intramuscular injection. A number of other iodin compounds as lipojodin, jodipin, jodostarin, jodal, jodoform, jodathylhexamethylentetramin, dioradin, novojodin, sajodin, jodocithin, jodolen, etc., were ineffective in the same dose.

In my experiments the maximum tolerated dose of potassium iodid for rabbits by single intravenous injection was found to be about 0.310 gm. per kilogram of weight; sodium iodid was found very much less toxic being tolerated in doses as high as 2.5 gm. per kilogram (Table 1).

With the assistance of Dr. Malcolm J. Haskins, I have treated a series of rabbits with acute testicular syphilis (about five weeks after inoculation) with daily intravenous injections of potassium iodid in dose of 0.030 gm. per kilo of body weight for 10 days; other rabbits received the drug by stomach tube in dose of 0.1 g. per kilo daily for 10 doses. A third series received sodium iodid intravenously in dose of 0.060 gm. per kilo and a fourth series 0.12 gm. per kilo by stomach tube. These doses were therefore, quite large and corresponded to a daily dose of from 1.8 to 3.6 gm. intravenously and about 6 gm. orally for an adult human being of 60 kilograms. Yet ten consecutive doses of these amounts did not suffice to cure the disease in any rabbit. It is true that the spirochetes were influenced however, because they were reduced in numbers as compared with the untreated controls and in some instances the local testicular lesions healed more rapidly, but when lymph-gland transfers were made to fresh rabbits it was found that with one or two exceptions, living spirochetes were present.

When the iodids are administered to rabbits immediately after inoculation with *Sp. pallida* and the administrations continued at weekly or bi-weekly intervals for a period of four months, the infection is less severe, the lesions less numerous and of shorter duration than in similarly infected but untreated animals, as recently reported by Pearce.[5] In this connection it may be also stated that Akatsu[6] found that potassium iodid was but very feebly spirocheticidal *in vitro*. In his experiments 0.5 c.c. of solutions as strong as 1:10 were required to kill the pallida contained in 3 drops of culture in an exposure

of 1 hour at 37°C. Iodin in the form of Lugol's solution was spirocheticidal in dilution of 1:75.

A general view of these results indicates therefore, that the iodides possess but slight spirocheticidal activity even for *Sp. gallinarum* which is more readily destroyed than *Sp. pallida* and *Sp. pertenuis*. The intravenous injection of potassium iodid in large doses very probably aids in the direct destruction of *Sp. pallida* in the treatment of human syphilis; sodium iodid being 8 times less toxic may be administered in even larger doses for this purpose. But the oral administration of either in the doses commonly employed in the treatment of human syphilis probably has no direct spirocheticidal activity unless this property is enhanced when the drugs are given in combination with either mercury or arsphenamin. This subject is discussed, however, more fully in Chapter XXX and the results of experiments presented.

Mechanism of the Curative Activity of the Iodids in Syphilis.—While the iodids have, therefore, but a slight degree of spirocheticidal activity, an abundance of clinical data shows that the administration of these compounds greatly aids in the reduction and absorption of syphilitic exudates and gummas.

Many different theories have been advanced from time to time to explain the mechanism of this curative activity. Binz[7] and Hinz[8] believed its action to be due to the oxidizing properties of the nascent iodin, which according to Hinz, renders the blood-vessels more permeable and the leukocytes more active. Others have stated that iodin stimulates the activity of the lymphatics with a change in metabolism and an increase of nutritive processes in general promoting the absorption of disease products.

The best explanation has been given by Jobling and Petersen,[9] who believe that the unsaturated fatty acid radicals which act as antiferment and inhibit autolysis become saturated with iodin when the iodids are administered. As soon as this occurs, the ferments which are present in the syphilitic lesions, or which may be brought in, become active, autolysis takes place and the necrotic tissue is absorbed. Here, also, the local action of the ferments is made less difficult by the reduction of the antifrement in the circulating blood. In addition it should be realized that the iodin itself may exert minor degrees of spirocheticidal activity either directly or after the formation of some new compound in the tissues and Pearce is of the opinion that the drug may stimulate or reinforce the host's mechanism of reaction or defense.

Acquired Resistance of Spirochetes to Iodid.—Does *Sp. pallida* acquire an increased resistance to potassium iodid during the treatment of syphilis? This is an important question although since the therapeutic activity of the iodids in syphilis probably does not depend upon spirocheticidal activity to any marked extent, the question is of lesser importance than acquired resistance to the organic arsenical compounds and mercury.

As previously stated iodin is only feebly spirocheticidal *in vitro*. Akatsu and Noguchi found that it required the addition of as much as 0.7 c.c. of Lugol's solution to 5 c.c. of ascites broth medium to inhibit the growth of *Sp. pallida*, *Sp. microdentium* and *Sp. refringens*. By beginning with smaller amounts and gradually increasing with transfers every 2 or 3 weeks, it was found that resistance or tolerance was increased about three fold after 8 to 10 transfers covering a period of 3 to 4 months.

If similar resistance develops *in vivo*, it is probable that during the treatment of syphilis with potassium or sodium iodids that *Sp. pallida* may acquire some resistance to the spirocheticidal activity of these compounds.

CHAPTER XXVII

TOXICITY AND SPIROCHETICIDAL ACTIVITY OF COMPOUNDS OF QUININ AND OF ANTIMONY, VANADIUM, GOLD, THORIUM AND OTHER COMPOUNDS OF THE HEAVY METALS

Various other substances in addition to compounds of arsenic, mercury and bismuth have been tried in the treatment of spirochetic infections and especially of experimental syphilis of the rabbit. Most interest has been shown in the elements belonging to the same periodic arrangement as mercury and bismuth. Before taking up these other compounds, the spirocheticidal activity of quinin may be briefly discussed.

Spirocheticidal Properties of Quinin.—Since various salts of quinin are well known to be protoplasmic poisons, it is not surprising that quinin was among the substances early investigated in relation to its spirocheticidal properties. Neisser[1] injected 10 monkeys intravenously with *quinin bimuriate* in dose of 0.4 to 0.5 gm. per animal six days after inoculation and all developed syphilis. Two additional animals receiving the same compound by mouth or subcutaneous injection in dose of 3.75 gm. escaped the disease. All of nine monkeys treated in the same way seven days after inoculation developed the disease but of nine more animals treated in the same way with subcutaneous injections 8 days after inoculation, 4 were apparently cured. Of nine monkeys treated after the development of primary lesions with 0.1 to 0.3 gm. of *quinin bimuriate* per animal, 5 were apparently cured. Of 8 additional animals treated with 0.8 to 3.25 gm. by oral administration, 4 were apparently cured.

Schereschewsky[2] has recently reported that quinin salve was effective in preventing natural infection among rabbits by *Sp. cuniculi* (venereal spirochetosis).

It would appear, therefore, that quinin possesses a feeble degree of spirocheticidal activity but these compounds have not been generally employed in the treatment of human syphilis since their curative activity is exceeded by other substances. Quinin is, however, of comparatively low toxicity and the possibilities of improving these compounds for the treatment of spirochetic infections may profitably engage the interests of experimental chemotherapeutists.

Toxicity and Spirocheticidal Properties of Antimonyl Compounds.—As stated in Chapter XIII, antimonyl compounds and especially tartar emetic, possess a high degree of trypanocidal activity. On the basis of this knowl-

edge several investigators have been led to study the spirocheticidal properties of known and new compounds of antimony with the hope that equally good results could be obtained in the treatment of syphilis.

Dubois[3] studied the curative effects of several preparations by intravenous injection in syphilitic rabbits and found that while single doses in amounts equal to the maximum tolerated doses were without much effect, multiple doses of *antimony tartrate* sometimes effected a disappearance of spirochetes from the lesions. When the compound was administered in dose of 0.01 gm. per kilogram along with arsenophenylglycin in dose of 0.01 to 0.03 gm., curative effects were usually observed after two or three treatments. On the basis of these results Dubois thought that antimony may enhance the curative activity of the arsenical compounds and prove worthy in the treatment of human syphilis as a form of combination therapy.

Danysz has combined antimony and silver with arsphenamin in a compound designated as "*luargol*," as a form of combination therapy; the curative dose reported for rabbit syphilis is exceptionally small (0.003 gm. per kilogram) with a chemotherapeutic index of 60. It is probable, however, that while this amount sufficed for the temporary sterilization of the testicular lesions, it is insufficient for complete sterilization of the lymphatic glands.

Uhlenhuth, Mülzer and Hügel[4] and Hügel[5] have prepared a number of new antimonyl compounds which were studied for toxicity and curative activity in fowls infected with *Sp. gallinarum*. Their compounds showed chemotherapeutic indices ranging from 2 to 10, but since fowl spirillosis is so readily influenced it is very doubtful if similar results could be obtained in the treatment of rabbit syphilis, although they report that repeated doses had favorable effects upon *Sp. obermeieri* infections of mice and *Sp. pallida* infections of rabbits.

Hügel[6] observed that the maximum tolerated dose of *potassium antimonyl tartrate* (tartar emetic) for the rabbit was about 0.010 gm. per kilogram by intravenous injection. When this dose was administered to syphilitic rabbits, the lesions showed only non-motile spirochetes the following day but active organisms were again found on the third day. Almost identical results were observed by Klauder[7] with this substance. Klauder also found that *antimony tartrate* in maximum tolerated dose by intravenous injection (0.015 gm. per kilogram) had a similar effect. When administered by intramuscular injection in dose of 0.050 gm. per kilogram, the spirochetes promptly disappeared from the testicular lesions but the animal succumbed in 48 hours.

It may be stated, therefore, that the antimony compounds included in these studies possess but feeble spirocheticidal properties being even less active in this regard than compounds of mercury. However, they are not entirely devoid of spirocheticidal properties and antimony may profitably command further study from the standpoint of producing compounds of lesser toxicity (like sodium antimony thioglycollate of Rountree and Abel) and probably greater spirocheticidal activity.

Toxicity and Spirocheticidal Properties of Vanadium.—Since vanadium belongs to the fifth group of the periodic system of elements in which we find such well-known spirocheticidal substances as compounds of arsenic, bismuth and antimony, Proescher and Seil[8] have studied the toxicity and spirocheticidal activity of a number of its salts. The same paper includes a clinical contribution by Stillians, who found that the salts of vanadium and especially sodium hexavanadate, possess spirocheticidal properties, quickly destroying spirochetes in chancres and mucous patches of human subjects.

This investigation included fourteen compounds of vanadium embracing vanadates, vanadites and vanadyl salts, as well as the more complex derivatives with the oxides of arsenic, antimony and phosphorous. Elaborate chemical, toxicological and various therapeutic studies were made. The toxicity of the vanadium salts appeared to depend on their chemical constitution and was influenced by the number of hydroxyl groups attached to a vanadium atom and the presence of the double bonded oxygen (VO_2 group). Toxicity tests in rabbits by intravenous injection and in guinea pigs, rats and mice by subcutaneous injection, showed that ammonium metavanadate was most toxic (0.0002 gm. per kilogram) and sodium hexavanadate least toxic (0.030–0.040 gm. per kilogram), both values being expressed in terms of vanadium pentoxid (V_2O_5). In experimental animals and human beings, the salts of vanadium may produce nephritis with albumin and casts in the urine as well as gastro-intestinal irritation.

In the treatment of rabbit syphilis Proescher and Seil found that sodium tetravanadate, sodium hexavanadate and vanadyl sulphate injected intravenously in amounts corresponding to about two thirds the maximum tolerated doses, caused a disappearance of spirochetes in scrotal lesions but whether these were curative in the sense of effecting complete sterilization of the lymphatic glands, cannot be stated. Proescher and Seil thought that the spirocheticidal properties were due to the vanadium injected and independent of the salt employed. Negative results were observed in the treatment of rats infected with *Sp. novyi*, but details of these experiments were not given.

Spirocheticidal Activity of Compounds of Gold, Thorium, Germanium, Zinc, Calcium, Tin, Strontium, Cerium, Cadmium, Tungsten, Uranium, Barium and Platinum.—Continuing researches along the same lines, Klauder[9] has studied the spirocheticidal properties of other elementary metals belonging to the fifth group of periodic arrangement and showing possible chemical relationship. This work was conducted by comparing various salts of these elements with the spirocheticidal and symptomatic effects following the intravenous injection of 0.006 gm. arsphenamin per kilogram of weight in rabbits with well-developed syphilitic lesions of the testicles. This dose of arsphenamin is only one half the curative dose but is sufficient for producing primary effects in the testicles and for purposes of comparison without the additional time and extra animals required for determining the minimal amounts necessary for effecting complete sterilization of the lymphatic glands.

Gold chlorid, which has been used in the past in the treatment of locomotor ataxia and other diseases of the central nervous system, was administered intramuscularly in doses of 0.1 to 0.2 gm. per kilogram of weight. Following the 0.1 gm. dose there were no gross changes in the testicular lesion for about five days, but complete involution occurred in sixteen days. Dark-field examination twenty-four hours after treatment showed many non-motile spirochetes (before treatment many very motile spirochetes were present), but an absence of spirochetes was not noted until the sixth day after treatment. Since a similar result is within the limit of the rate of disappearance of the syphiloma and of spirochetes in untreated animals, this amount of gold chlorid was not regarded as exerting spirocheticidal action.

Following treatment with 0.150 gm. of gold chlorid, the syphiloma involuted in twelve days; the dark-field examination was negative in three days. This amount, therefore, furnished evidence of some spirocheticidal activity. Treatment with 0.200 gm. killed the animal in five days but until this time there was little evidence of spirocheticidal activity of the drug. It is apparent, therefore, that maximum doses of gold chlorid do not possess the spirocheticidal activity of 0.006 gm. arsphenamin per kilogram, but nevertheless gold is not entirely lacking in this property. Insofar as effect upon rabbit syphilis is concerned, gold chlorid in single maximum tolerated doses exerts almost as much spirocheticidal action as the salts of mercury.

Thorium chlorid demonstrated some spirocheticidal activity. The intramuscular injection of 0.100 gm. per kilo produced a partial involution of the syphiloma during the following ten days; the dark-field examination became negative the sixth day after treatment, but showed spirochetes again in fifteen days, at which time the syphiloma was well pronounced. Treatment with 0.125 gm. per kilogram produced a marked improvement of the syphiloma in ten days and involution in seventeen days; the dark-field examination became negative in six days and there was no recurrence over a period of observation of sixty days. Two animals were treated with 0.150 gm. of thorium chlorid per kilogram. In one there occurred an involution of the syphiloma in nine days and the dark field examination became negative in two days. The second showed a marked improvement of the syphiloma two days following treatment, but complete involution did not occur until two weeks; the dark-field examination became negative in six days.

Thorium chlorid, therefore, is not entirely devoid of spirocheticidal properties and in single maximum tolerated doses exerts a curative effect in rabbit syphilis analogous to that of vanadium, gold and even mercury.

All other salts of these elements including *germanium*, *zinc*, *calcium*, *tin*, *strontium*, *cadmium*, *tungsten*, *uranium*, *barium* and *platinum*, yielded negative results when administered in single doses of 0.100 to 0.125 gm. per kilogram (germanium 0.005 to 0.025 gm.) by intramuscular injection. Dark-field examinations of the testicular lesions made one, two and more days after treatment showed no influence upon numbers and motility of spirochetes. Most interest was commanded by germanium oxide on account of its close relationship to arsenic, but this substance possesses neither trypanocidal nor spirocheticidal properties in single maximum tolerated doses. Strontium and platinum have been com-

bined with arsphenamin and these compounds possess well marked spirocheticidal properties, but the simple chlorides of the metals themselves are devoid of spirocheticidal activity.

Neisser[10] has studied the prophylactic and curative properties of various colloidal preparations of the heavy metals in syphilis of monkeys. Of eight animals treated with 0.1 to 0.25 gm. of *collargol* by intravenous injection of 1-per cent. solutions after the development of primary lesions, 4 were apparently cured and 4 were not. Eighteen monkeys treated with 13–30 c.c. of *elektrargol* were not cured. Six monkeys treated with 16–20 c.c. of *elektropalladiol* were not cured but two additional monkeys treated 5 days after inoculation, escaped syphilis. Of ten monkeys treated with *elektroplatinol* 5 to 6 days after inoculation, 9 developed syphilis. All of 7 animals treated with 15 c.c. of *elektraurol* immediately after inoculation developed the disease; likewise all of 8 additional monkeys treated with *cuprol* by oral administration (3.75 gm. in 30 days). Six monkeys treated with *cuprargol* by oral administration (3.75 gm. in 3 weeks) were not cured.

CHAPTER XXVIII

SPIROCHETICIDAL PROPERTIES OF ARSPHENAMIN, NEOARSPHENAMIN, MERCURIAL AND OTHER COMPOUNDS IN VITRO

The results of test tube or *in vitro* spirocheticidal tests are greatly influenced by the technic employed. It is not possible to compare the results observed by one investigator with the results of others unless the same method has been used. For this reason the results of spirocheticidal tests *in vitro* should be evaluated only in a broad and general manner.

These tests, however, are not without some practical significance. As discussed in Chapter IV, *in vitro* bacteriostatic and bactericidal tests have a definite value in chemotherapeutic research and the same may be said of spirocheticidal tests, since we now have available methods for cultivating various pathogenic species. Furthermore, they have some application to the treatment of local infections like Vincent's angina and spirochetic gingivitis by the local application of spirocheticidal substances; likewise to the prophylaxis of syphilis, as shown by the investigations of Reasoner[1] and others discussed in more detail in the chapter devoted to the prophylaxis of syphilis.

Hata found that a 1:4000 solution of salvarsan destroyed the motility of *Sp. obermeieri* in the test tube and actually killed the organisms as determined by injecting a portion of the mixture into mice. However, controls of 1:4000 solutions containing the same amount of sodium hydroxid as in the salvarsan solution yielded the same results.

Castelli[2] found that in mixtures of 1 c.c. of varying dilutions of neosalvarsan up to 1:1000 in saline solution and 1 c.c. of chicken blood containing *Sp. gallinarum* kept at room temperature for one hour followed by the injection of 0.3 c.c. of the mixtures into fowls, there was no evidence of an actual destruction of these spirochetes. Similar experiments with *Sp. obermeieri* showed that while neosalvarsan was unable to kill the organisms in dilutions up to 1:1000, the virulence or infectivity of the spirochetes was reduced for

mice. Hahn and Kostenbader[3] reported that a fluorescin mercury compound capable of curing *Sp. gallinarum* infections of fowls in dose of 0.008 gm. per kilogram (maximum tolerated dose 0.018 gm.) was without effect *in vitro* when mixed with blood containing the spirochetes for 15 to 45 minutes followed by intramuscular injection into chickens to determine spirocheticidal effects.

On the basis of these experiments, both Ehrlich and Hata taught that salvarsan possessed no spirocheticidal activity *in vitro*. This view is still maintained by many physicians, although it has since been shown by Neufeld and Böcker[4] that salvarsan and neosalvarsan are able to kill *Sp. gallinarum* in the test-tube and that both substances possess spirocheticidal properties *in vitro* for suspensions of *Sp. pallida*.

Noguchi and Bronfenfrenner,[5] for example, mixed 0.1 c.c. of culture with 0.5 c.c. of varying dilutions of salvarsan and after one hour at room temperature cultured the mixture in the ascites kidney agar medium of Noguchi. Controls were included of the sodium hydroxid alone. Salvarsan was found to kill *Sp. pallida* under these conditions in dilutions as high as 1:1000; similar results were observed with cultures of *Sp. refringens*, *Sp. mucosum* and *Sp. microdentium*. Sodium hydroxid in dose of 0.5 c.c. of $\frac{N}{10}$ to $\frac{N}{30}$ strength killed 0.1 c.c. of the various cultures in the exposure of one hour.

Noguchi and Bronfenbrenner also found that arsenious acid possessed a high degree of spirocheticidal activity *in vitro* although this compound does not influence spirochetic infections of the lower animals even in maximum tolerated doses. Mercuric chlorid was spirocheticidal in dilutions as high as 1:200,000 and tricresol and phenol in dilutions of 1:200 to 1:500. In comparative tests with a culture of *B. coli*, it was found that all of these substances were from 20 to 100 times more toxic for spirochetes than for the bacillus.

Noguchi and Bronfenbrenner also made the interesting observation that the spirocheticidal activity of salvarsan was increased two to five times in the presence of defibrinated rabbit blood and fresh emulsions of rabbit liver. For example, a 1:1000 solution of salvarsan in saline solution was spirocheticidal but a 1:2000 dilution in a fresh unheated extract of liver and a 1:5000 dilution in rabbit blood were equally spirocheticidal. Since a solution in a boiled extract of liver was spirocheticidal only in 1:700, Noguchi and Bronfenbrenner thought that the liver enzymes increased spirocheticidal activity, a view somewhat similar to that expressed by Levaditi. These results are not without significance in view of the fact that arsenic is stored in the liver after the administration of arsphenamin and neoarsphenamin; furthermore, the liver is more subject to the toxic action of these compounds than any other organ, as discussed in Chapter XLVI.

Schamberg, Raiziss and myself[6] determined the spirocheticidal activity of salvarsan and mercuric chlorid by mixing 1 c.c. of varying dilutions of each with 1 c.c. of *Spirochæta pallida* culture (Zinsser's strain A) and after two hours in the water bath at 37°C., 10 c.c. of ascites-kidney agar and a piece of sterile kidney were added under anerobic conditions for several weeks and examined after the controls showed good growths. Under these conditions it is possible that the compounds continued to exert some spirocheticidal activity throughout the period of incubation. Different lots of arsphenamin were spirocheticidal under these conditions in dilutions varying from 1:2000 to 1:128,000; mercuric chlorid was spirocheticidal in dilution of 1:160.

In a later study by Akatsu[7] in Noguchi's laboratory, additional evidence was produced showing that salvarsan and neosalvarsan possessed spirocheticidal activity *in vitro*. Akatsu prepared solutions of these and other compounds in distilled water and to 1 c.c. of each dilution added three drops of culture. After standing one hour in a water bath at 37°C. transplants were made to Noguchi's ascites agar medium and the cultures incubated anerobically for several weeks. With this method Akatsu found that salvarsan was spirocheticidal in dilutions as high as 1:7500. Neosalvarsan was less toxic for *Sp. pallida*, since the highest spirocheticidal solution was 1:2500. Mercuric chlorid had a value of 1:100,000; phenol, 1:2500; lysol, 1:500; formalin, 1:750, etc. Sodium cholate, sodium glycocholate and taurocholate and sodium oleate were likewise highly toxic proving spirocheticidal in dilution of 1:2500 to 1:7500 and confirming the observations of Neufeld and von Prowazek[8] and Gonder[9] that spirochetes, unlike bacteria in general, are highly susceptible to the lytic action of sodium taurocholate and saponin. Akatsu also found that 76 of the new quarternary salts of hexamethylene tetramin compounds prepared by Jacobs and Heidelberger,[10] possessed spirocheticidal properties in dilutions of 1:50 to 1:50,000.

Lee[11] has studied the spirocheticidal activity of salvarsan and neosalvarsan by mixing a drop of varying dilutions on slides with a drop of a suspension of *Sp. pallida* obtained from well developed chancres or mucous patches of human subjects. By sealing with vaseline to prevent evaporation it was possible to study the motility and morphology of the spirochetes with the dark field illuminator for 8 hours or longer. With this method Lee found that 1:130 solutions of arsphenamin, neoarsphenamin and silver arsphenamin were without effect upon the spirochetes; likewise arsphenaminized and neoarsphenaminized serum from blood drawn two to forty-eight hours after the intravenous injection of these com-

pounds. On the other hand an emulsion of tissue removed from a syphilitic lesion showing a reaction of hyperemia after the injection of salvarsan was highly spirocheticidal. On the basis of these results, Lee believes that salvarsan exerts its spirocheticidal properties by first combining with the protein of cells forming an "arsenoprotein" detrimental to *Sp. pallida*, whereas the mercury salts are direct chemical poisons.

Greenbaum, working in my laboratory, employed a similar method for determining the toxicity of arsphenamin, neoarsphenamin, arsenious acid, mercurophen, mercuric chlorid and other substances for the numerous kinds of spirochetes in the secretions of the gums of human subjects with spirochetic gingivitis. Slides were prepared by mixing one loopful of gingival spirochete emulsion with one loopful of solution of drug followed by sealing and study with the dark field illuminator at frequent intervals up to 2 hours. The following results were observed, the dilutions indicating the highest required to effect complete loss of motility of the spirochetes with morphological changes: Arsphenamin, 1:200 instantaneous; 1:500 required 1 to 2 hours. Neoarsphenamin 1:50 instantaneous; 1:100 required 1 to 2 hours. Mercurophen and mercuric chlorid 1:6000 instantaneous. Arsenious acid, and iodin 1:50 had no effect. These results show that arsphenamin, neoarsphenamin and mercurical compounds are able to exert a toxic effect upon spirochetes in the presence of inflammatory exudates and I shall refer again to these studies in a later chapter dealing with the local treatment of spirochetic gingivitis with solutions of arsphenamin.

Weiss and Wilkes working in my laboratory, have brought forward additional evidence showing the spirocheticidal activity of arsphenamin, neoarsphenamin and other substances *in vitro*. They have prepared isotonic solutions of each substance in varying strengths and mixed 0.5 c.c. of each in test tubes with 0.5 c.c. of *Sp. pallida* cultures. These mixtures were placed in a water bath at 37°C. and at varying intervals each mixture was examined for the motility of spirochetes and cultured anerobically in gelatinized horse serum for the viability of the organisms. The pH of each solution of arsphenamin and neoarsphenamin was determined and control solutions of isotonic saline prepared with the same pH reaction. In this way the influence of alkali upon the spirochetes was adequately checked.

Both arsphenamin and neoarsphenamin brought about a loss of motility and death of the spirochetes in dilutions of 1:200 to 1:1000, arsphenamin being the more toxic. Since the control solutions in 1:200 were not toxic the results prove conclusively that both compounds are spirocheticidal *in vitro*. The spirocheticidal activity of copper sulphate, halozone and mercurophen was also shown. Brilliant green, however, was not spirocheticidal in dilution of 1:1000 although this strength was highly bactericidal.

Finally, I have been able to show the well defined spirocheticidal activity of arsphenamin, neoarsphenamin and mercuric chlorid *in vitro* by mixing 0.5 c.c. of varying isotonic dilutions in test tubes with 0.5 c.c. of an emulsion of virulent *Sp. pallida* secured by emulsifying rabbit syphilitic testicles containing numerous actively motile spirochetes. These mixtures were kept in a water bath for 15 minutes, examined for motility and 0.5 c.c. of each injected into the testicles of rabbits. The animals were then kept under observation for several months. A dilution of 1:400 of arsphenamin destroyed motility and 1:1600 was spirocheticidal. Neoarsphenamin in dilution of 1:200 reduced motility and 1:1600 was spirocheticidal, being less toxic for the organisms than arsphenamin in both tests. Mercuric chlorid destroyed motility in 1:10,000 and was spirocheticidal in at least 1:20,000 being at least several times more spirocheticidal *in vitro* than either arsphenamin or neoarsphenamin. Gruhzit[12] has observed that mercurosal is less spirocheticidal *in vitro* for *Spirochaeta novyi* and *Spirochaeta pallida* than the inorganic mercurials; the latter appeared to be from five to seven times less resistant than *Spirochaeta novyi*. For example, 1:25,000 mercurosal destroyed the motility of *Spirochaeta pallida* in one hour but *Spirochaeta novyi* required 1:10,000; the motility of both spirochaetes however, was instantly destroyed by mercuric chlorid and iodid of mercury in these dilutions.

A general review of the results recorded shows, therefore, that both arsphenamin and neoarsphenamin possess spirocheticidal properties *in vitro* for various spirochetes. However, these toxic effects are apparently far more evident with cultures of spirochetes than with spirochetes in inflammatory exudates. Whether or not the curative action of the organic arsenicals in the living animal can be explained on the basis of direct spirocheticidal action of arsphenamin and neoarsphenamin as such or in the form of their oxides, is still an open question. The mercurials are especially toxic for spirochetes *in vitro* and if their effect *in vivo* were a simple direct one it would be expected that they would show more curative effects. Even though 0.002–0.003 gm. of mercuric chlorid per kilogram is the maximum tolerated dose, yet the intravenous injection of these amounts has no effect upon trypanoso-

miasis or rabbit syphilis while a similar dose of arsphenamin brings about a partial sterilization and even a cure in some instances. Since mercuric chlorid is more than 10 times more spirocheticidal than arsphenamin *in vitro*, it is apparent that the mechanism of spirocheticidal activity *in vivo*, which reduces the parasitropism of mercury and increases that of arsphenamin and neoarsphenamin, is a far more complicated process than direct chemical toxicity of these substances for various spirochetes.

Since *bismuth* has become widely employed in the treatment of syphilis, considerable interest is attached to the effects of its soluble salts upon *Spirochaeto pallida in vitro*. With the assistance of Miss Anna Rule, I have studied the influence of potassium tartrobismuthate and sodium tartrobismuthate upon spirochetes derived from acute testicular lesions of rabbits; final dilutions as concentrated as 1:20 were required to produce loss of motility of all spirochetes in 5 minutes at 38°C.; with an exposure of 30 minutes at this temperature loss of motility occurred in final dilutions of about 1:80. Saline controls kept at 37°C. showed loss of motility in 60 minutes but controls kept at room temperature showed no loss of motility in 2 hours, indicating that saline solution was much more toxic for these spirochetes at 37°C. than at approximately 20°C.

CHAPTER XXIX

METHODS OF ADMINISTRATION IN RELATION TO THE CHEMOTHERAPY OF EXPERIMENTAL SYPHILIS

In the preceding chapters the minimal curative doses of various arsenical, mercurial bismuth and other compounds for syphilitic infections of rabbits, have been generally expressed according to the smallest amounts per kilo of weight capable of dissipating the local lesions and sterilizing the lymph-glands. These amounts are summarized in Chapter LXVII but are too large for administration to human beings when given according to body weight, because of toxic effects. The hope of *magna therapie sterilisans* in the treatment of human syphilis has been abandoned, at least for the present time, and multiple doses are given which renders important the subject of intervals between administrations. Under ordinary circumstances syphilis of the rabbit is much milder than syphilis of the human being, although suppression of the primary lesion sometimes results in the widespread distribution of

spirochetes with the production of lesions of the skin and mucous membranes, lymph glands, bones, special organs, etc., similar to the lesions of syphilis in the human being. But natural immunity in the rabbit to *Spirochaeta pallida* is more marked than in human beings; likewise, the immunity response in untreated and treated syphilis of this animal is more decided and these factors render the cure of syphilis of the rabbit much easier of accomplishment than syphilis of human beings; however, data of much value may be obtained from well conducted experiments employing these animals.

Importance of Intervals between Administration of Medicaments in the Treatment of Acute Syphilis of Rabbits.—It is difficult to express the comparative curative values of antisyphilitic medicaments in divided doses, because of the marked variation in results with rabbits and the very large number of tests required in order to obtain general and average results. However, with a few of the antisyphilitic remedies fairly accurate figures have been obtained and these have indicated that *when the treatments are given once a week, the total amounts required for effecting a complete cure in the primary stage of syphilis are greater than when the medicaments are given at shorter intervals.* Apparently in the longer intervals of administration of medicaments in amounts less than the single curative dose, surviving spirochetes are enabled to proliferate, acquire some degree of fastness or by some other agency require a higher *total* amount of the compound to effect complete sterilization than is the case when the medicament is given in a single large dose or in smaller amounts at daily or two day intervals. These results are shown in the following table:

Compound	Total Required per Kilo in One Dose (Gm.)	Total Required per Kilo in 3 Doses Given at Daily Intervals (Gm.)	Total Required per Kilo in 4 Doses Given Twice Weekly (Gm.)	Total Required per Kilo Given in 6 Doses Once a Week (Gm.)
Arsphenamin	0.012	0.015	0.024	0.048
Neoarsphenamin	0.020	0.024	0.040	0.090
Sod. and potass. tartro-bismuthate	0 050	0.060	0.060	0.090

In the treatment of acute primary testicular syphilis of the rabbit, *the intervals between the administration of medicaments is, therefore, a matter of considerable importance* and the same has been found true in the treatment of trypanosomiasis of these animals with the pentavalent and trivalent organic arsenical compounds; indeed, proper spacing of the injections is almost as important as the size and number of doses.

Comparative Study of Methods for the Administration of Arsphenamin, Neoarsphenamin, and Bismuth in the Treatment of Chronic Syphilis of Rabbits.—In the treatment of chronic syphilis of the rabbit however different results have been observed. By inoculating large numbers of rabbits and castrating seven to fourteen days later to promote dissemination of the infection, a sufficient number were suitable for chemotherapeutic studies from six to eight weeks later. In the majority of instances the animals showed some loss in weight with lymphatic, cutaneous, muco-cutaneous and periosteal lesions. The Wassermann reactions, conducted according to my new method, showed fixation with 0.025 c.c. and smaller amounts of serum; amounts greater than 0.025 c.c. were not employed, in order to avoid the non-specific reactions sometimes encountered with the sera of normal rabbits.

The criteria of cure in these experiments, conducted with the assistance of Miss Anna Rule, were disappearance of the lesions, a reduction of the complement-fixation reactions and *negative rabbit inoculation tests with emulsions of lymph-glands.* The latter was regarded as the best evidence, because, as shown by Brown and Pearce and amply confirmed by us, living *Sp. pallida* may be found in the inguinal and popliteal lymph-glands in cases of extreme latency and apparent cures. The medicaments selected were arsphenamin (disodium salt), neoarsphenamin and sodium and potassium tartro-bismuthate, all except the bismuth being administered by intravenous injection in order to render dosage and absorption as accurate as possible. The total amount required for effecting cures of the majority (not all) of the rabbits were approximately as summarized in the following table:

Compound	Total Required per Kilo in One Dose (Gm.)	Total Required per Kilo in 6 Doses Given Twice Weekly (Gm.)	Total Required per Kilo in 6 Doses Given Once a Week (Gm.)
Arsphenamin	0.030	0.090 to 0.120	0.080 to 0.100
Neoarsphenamin	0.050	0.120 to 0.250	0.110 to 0.240
Bismuth	0.090	0.06 to 0.180	0.06 to 0.160

It will be noted that the single curative doses were two to three times larger than required for the cure of acute testicular syphilis and in the case of bismuth, about one-half the maximum tolerated dose, even though this amount was not always curative. The single curative doses, while less than the *total* amounts required when injected once or twice weekly, are altogether too large and out of question in relation to the treatment of chronic syphilis of human beings; therefore it is interesting to note that the *total* amounts of the various medicaments required when given once a week were slightly less than when given twice a week. Furthermore, fewer animals were lost by the once a week plan. These experiments have also shown that in the treatment of the cutaneous, muco-cutaneous and periosteal lesions of rabbits, better results were secured with arsphenamin and neoarsphenamin than with bismuth and mercury. These lesions in the rabbit can be interpreted as chronic lesions of mild degree, even though they developed and were usually treated within a period of four months after inoculation. The trivalent arsenical compounds, at least, were apparently more penetrative and curative than the bismuth preparation in these experiments and were less toxic in divided doses at intervals of administration of about three days.

Comparative Study of Methods for the Administration of Mercury in the Treatment of Chronic Syphilis of Rabbits.—In Chapter LII I have discussed the influence of route of administration of mercurial compounds upon toxicity; here may be recorded a summary of experiments bearing upon the influence of route of administration upon curative activity in chronic syphilis of the rabbit. In conducting these experiments the following three mercurial compounds were chosen for intravenous, intramuscular and cutaneous administration in amounts per kilogram of body weight, corresponding closely to the amounts commonly employed in the treatment of syphilis of human subjects based upon 130 pounds of weight. (a) *Mercuric chlorid* by intravenous injection in dose of 0.00025 gm. per kilo (corresponds to ¼ grain per 130 pounds), twice a week. (b) *Mercuric chlorid* by intramuscular injection in same dose once per week. (c) *Salicylate of mercury* by intramuscular injection in dose of 0.001 gm. per kilo (corresponds to 1 grain per 130 pounds), once a week. (d) *Mercurial ointment* (U.S.P.) by inunction in dose of 0.06 gm. per kilo (corresponds to one drahm per 130 pounds), once a day. For administration the ointment was diluted with benzoated lard and lanolin to permit the application of larger bulk and consequently with less opportunity for error. Since the ointment contained 33 per cent. of metallic mercury, the dose of 0.06 gm. per kilogram corresponded to about 0.02 gm. of mercury.

The results summarized in the following table shows the approximate number of doses required for effecting cures in at least 75 per cent. of each of the three groups of animals:

Compounds	Per Cent. Mercury	Dose per Kilo (Gm.)	Route of Administration	Not Curative	Curative	Total Amount Sometimes Curative (Gm. per Kilo)
Mercuric chlorid	74	0.00025	Intraven.	12 doses	30 doses	0.0075
Mercuric chlorid	74	0.00025	Intramus.	10 doses	42 doses	0.0105
Salicylate mercury	45	0.001	Intramus.	15 doses	38 doses	0.038
Mercurial ointment	33	0.06	Cutaneous	24 doses	45 doses	2.7

It was not possible to obtain more accurate data without greatly increasing the labor and expense of the study, because of the large number of rabbits required for furnishing a suitable number of cases presenting approximately similar lesions for the four different forms of treatment. But the results are regarded as approximately correct and indicate the following:

(a) Best results were observed with the intravenous injection of a soluble salt of mercury (mercuric chlorid). The lesions and Wassermann reaction were dissipated more promptly and the total amount of mercury required for cures was less than with other routes of administration.

(b) Next best results were observed, in the order named, with intramuscular injections of a soluble mercurial compound (mercuric chlorid), an insoluble compound by intramuscular injection (salicylate) and metallic mercury by inunction (blue ointment).

(c) Insofar as mercuric chlorid and the salicylate are concerned, it would appear that the compounds are equally curative when judged upon the basis of actual amounts of metallic mercury administered. Mercury salicylate cures more slowly, owing to slower absorption of mercury, but the differences in curative activity of mercuric chlorid, the salicylate and the ointment depend upon different rates of absorption of mercury. After absorption has occurred, the mercury in each is probably of equal curative activity, just as the toxicity of these compounds appears to bear a relation to the actual amounts of mercury absorbed irrespective of the kind of compound or route of administration. A combination of these compounds, as arsphenamin or neoarsphenamin with a mercurial, yielded somewhat better results in treatment than a single compound and especially when injected intravenously. This subject is discussed in the following chapter: likewise, the curative activity of potassium iodid in chronic syphilis of the rabbit when administered with an arsenical or mercurial compound.

Intravenous versus Intramuscular Injection of Antisyphilitic Drugs.—Within recent years there has been an increasing tendency to administer antisyphilitic drugs intravenously in the treatment of human syphilis whenever conditions permitted this route of administration. When arsphenamin was first introduced by Ehrlich, intramuscular injection was employed, but it was soon found that this procedure produced great pain and tissue necrosis at the site of injection. To overcome this difficulty, the intravenous injection of the alkalinized solution (disodium salt) was introduced, and this method subsequently met with universal adoption. It was hoped that neoarsphenamin would overcome these difficulties of intramuscular injection, but it was soon found that even this compound causes considerable local reaction, although the degree of irritation may be diminished by the use of an oil suspension instead of a water solution. Still more recently, sulfarsenol or sulpharsphenamin have been introduced for subcutaneous and intramuscular injection, and these produce even less local irritation than neoarsphenamin in the majority of persons.

Many other factors require consideration in addition to this important one of local reaction in relation to the route of administration, not only of the arsenobenzenes but of mercury and bismuth as well, in the treatment of syphilis. For example, the rapidity and degree of absorption and elimination are of considerable importance as discussed in Chapter XLIII as well as general toxic effects and therapeutic activity. In general terms it may be stated that while intravenous injections may be painless, the chances of producing general toxic reactions are greater with all antisyphilitic drugs than by intramuscular injection. It is apparent, however, that the subject cannot be dismissed with a few brief and superficial statements and at this time I shall discuss the subject only from the standpoint of comparative curative activity in experimental infections of the lower animals, leaving for subsequent chapters a discussion of the subject from the standpoint of local and general toxic reactions, absorption and elimination and practical applications in the treatment of human syphilis.

Rabbits inoculated intratesticularly and treated after the development of large acute lesions with numerous actively motile spirochetes, have shown the following *minimal curative doses per kilo-gram of weight*, these amounts being approximately the smallest doses required not only for the dissipation of the testicular lesions and spirochetes but sterilization of the lymphatic glands as well:

Arsphenamin (disodium salt) intravenously	0.012 gm.
Arsphenamin (olive oil) intramuscularly	0.015 gm.
Neoarsphenamin (water) intravenously	0.015 gm.
Neoarsphenamin (olive oil) intramuscularly	0.015 gm.
Sulpharsphenamin intravenously	0.022
Sulpharsphenamin (water) intramuscularly	0.016

Owing to the feeble spirocheticidal activities of mercury and bismuth compounds, comparative tests of this kind have not yielded as definite information as the arsenobezene compounds. Experiments with rabbit syphilis, however, have shown that repeated intramuscular injections of soluble mercurial compounds, as mercurophen and flumerin, have yielded practically the same results as repeated intravenous injections of the same compounds in the same doses per kilogram of weight; it is highly probable that the same holds true for other soluble salts employed for the treatment of syphilis, although the curative activity of the insoluble salts as calomel and the salicylate emulsified in oil, is slightly less curative than the soluble salts administered by intravenous injection.

Intramuscular injections of solutions of bismuth salts (sodium tartro-bismuthate, potassium tartro-bismuthate, sodium and potassium tartro-bismuthate) in water have yielded approximately the same single minimal curative doses per kilogram of weight in rabbit syphilis as intravenous injections of these compounds. Suspensions of these salts in sterile olive oil injected intramuscularly have been, however, slightly less curative than intravenous injections of the compounds dissolved in water. Unfortunately, the bismuth salts are quite toxic by intravenous injection and solutions in water produce rather severe local reactions upon intramuscular injection, but the curative activity of intramuscular injections of emulsions in olive oil is only slightly less than intravenous and intramuscular injections of these salts dissolved in sterile water.

Experiments have shown, therefore, that intramuscular injections of the arsenobenzenes, mercury and bismuth compounds possess almost, if not more, curative activity as intravenous injections in the treatment of syphilis of rabbits when the same doses are administered per kilogram of weight. Of course, the effects of intramuscular injections are slower and especially after the injection of emulsions in olive oil, which reduces the value of intramuscular injections in the treatment of acute infections, but the ultimate effects of intramuscular injections of soluble antisyphilitic compounds are approximately the same as observed after the intravenous injection of these. The main advantages of intramuscular injections are greater freedom from general toxic reactions, slower absorption, slower elimination and thereby a longer range of therapeutic activity; the chief disadvantages are local pain, necrosis and disability when adequate doses are administered. The discovery of an organic arsenical compound possessing the same or higher therapeutic efficiency as arsphenamin and neoarsphenamin, but which may be administered intramuscularly or subcutaneously *in adequate and repeated doses*, will prove extremely useful in the treatment of human syphilis; at the present time sulpharsphenamin is best adapted for intramuscular or subcutaneous injection and is well borne by most individuals.

CHAPTER XXX

COMBINATION CHEMOTHERAPY OF EXPERIMENTAL SYPHILIS AND ITS RELATION TO THE TREATMENT OF HUMAN SYPHILIS

The subject of the combination therapy of syphilis is deservedly worthy of considerable attention since it would appear possible to increase the spiro-

cheticidal activities of two different compounds administered together beyond the summation of the effects of both separately without an increase of toxic effects. I have already discussed the subject in relation to the chemotherapy of experimental trypanosomiasis in Chapter XIX, stating that mixtures of arsphenamin and neoarsphenamin with certain mercurials and other compounds have sometimes increased trypanocidal effects beyond what could be expected from the compounds separately.

Kolle[1] believes that some mercurial compounds administered simultaneously with arsphenamin or neoarsphenamin hastens the transformation of the latter into therapeutically active substances without an increased toxicity. Bergel[2] also states that combined treatment yields best results, but believes that the mercury releases from the lymphocytes a lipolytic ferment which is spirocheticidal and thereby supplementing the curative effects of arsphenamin or neoarphenamin.

Apparently best results have followed when solutions of the arsenical and mercurial compounds were mixed and injected together, as in Linsser's method of combination therapy of human syphilis. As stated in Chapter XXIV, attempts toward evolving compounds of organic arsenic and mercury have so far failed to produce substances of distinctive curative properties although more recent attempts in combining arsenic and bismuth are apparently more successful. Kolle states that mixtures of salvarsan and mercuric chlorid or neosilversalvarsan and novasural are not the same as the metal (silver, gold, platinum, etc.) salvarsans, because the mercury does not enter into chemical union with the arsenic molecule; colloidal mixtures only are produced which tend to precipitate (Tyndall's phenomen) and especially mixtures of bichlorid and arsphenamin. Mixtures of novasurol and neosalvarsan remain clear and I observed similar results with mixtures of mercurophen and flumerin with arsphenamin or neoarsphenamin.

Kolle has found that the single minimum curative dose of neosilversalvarsan for scrotal chancres and testicular lesions of rabbits was about 0.010 to 0.015 gm. per kilogram by intravenous injection; novasurol was usually curative in a single dose of 0.015 gm. per kilo. In mixtures, however, spirocheticidal activity was increased with smaller amounts of each. For example, 0.007 gm. neosilversalvarsan plus 0.004 gm. novasurol per kilogram usually proved curative, insofar, at least, as to bring about a disappearance of spirochetes in five days with healing of the lesions, which were accepted as the criteria of therapeutic activity in all of his experiments.

I have observed essentially similar results to the extent that the simultaneous use of arsphenamin or neoarsphenamin with a mercurial compound have shown an increase of curative activity in syphilis of the rabbit beyond that exhibited by the arsenical compounds, even though the mercury compound alone was without demonstrable curative activity in the amounts employed.

Combination Therapy of Acute Testicular Syphilis of Rabbits.—In conducting these experiments rabbits were inoculated in the testicles and treated when the lesions were at the acme of activity with numerous motile spirochetes in the secretions. The criteria of comparative spirocheticidal activity were the dissipation of the testicular lesions and the disappearance of spirochetes with inoculation tests of emulsions of lymph-glands removed from the treated animals. The results, however, can be reviewed only in a broad and general manner, as it was not possible to use the very large number of animals required for the frequent repetition of each test in order to secure finer differences in curative activity.

Arsphenamin in dose of 0.005 gm. per kilo caused a regression of lesions but did not produce a complete cure since the minimal curative dose is about 0.012 gm. per kilo; but when given simultaneously with mercurophen in dose of 0.001 gm. or 0.005 gm. of flumerin per kilo, complete cures were generally produced. Arsphenamin mixed with sodium iodid in dose as large as 0.050 gm. per kilo however, did not result in an increase of curative activity.

Similar results were observed with neoarsphenamin. This compound in dose of 0.008 gm. per kilo caused regression of the lesions but not complete sterilization. When administered with mercurophen and flumerin however, complete cures were frequently obtained. In both sets of experiments treatment with mercurophen alone was without any effect upon the lesions while flumerin alone sometimes caused a reduction in the spirochetes with a slight regression of the lesions but never a complete cure.

The results indicate therefore, that mixtures of arsphenamin or neoarsphenamin with mercurophen or flumerin were slightly more effective than the arsenobenzols alone; the same was true to some extent of mixtures of arsphenamin or neoarsphenamin with a water solution of sodium and potassium tartrobismuthate. The addition of sodium iodid in dose corresponding to 3.0 grams per 60 kilograms of weight to the solutions of arsphenamin and neoarsphenamin had no effect however, upon increasing spirocheticidal activity.

Combination Chemotherapy of Chronic Syphilis of Rabbits.—In these experiments rabbits were inoculated in one testicle and castrated ten days later to aid in the dissemination of the spirochetes. Treatment was begun about six to eight weeks later with animals showing cutaneous, muco-cutaneous, lymph-gland or periosteal lesions, etc. The criteria of cure were dissipation of the external and obvious lesions and negative lymph-gland transplants to the testicles of fresh animals.

Arsphenamin (0.005 gm. per kilo) or neoarsphenamin (0.008 gm. per kilo) were injected intravenously once a week for three weeks; at the same time salicylate of mercury (0.001 gm. per kilo) was injected intramuscularly and sodium iodid (0.02 gm. per kilo) administered orally in order to duplicate a commonly employed method for the treatment of chronic syphilis of human beings. In other words the various medicaments were administered separately but at the same time. Whether or not this constitutes combination therapy in the same sense as administering two compounds mixed together in the same syringe, I am unable to state, but at any rate the results have proven of much interest, since combination therapy of this kind is frequently employed in the treatment of chronic syphilis of human beings.

The arsphenamin (total dosage 0.015 gm. per kilogram) and neoarsphenamin (total dosage 0.024 gm. per kilogram) alone served to dissipate the external lesions in the majority of cases, but lymph-gland transplants were usually positive indicating that complete cure had not been accomplished. The salicylate of mercury had some curative effects in that skin and periosteal lesions were improved, but the lymph-gland transplants always yielded positive results. The sodium iodid alone had no appreciable effects.

Rabbits treated with the arsphenamin or neoarsphenamin and salicylate of mercury yielded the highest percentage of complete cures; the simultaneous oral administration of sodium iodid did not have an added curative activity in these experiments insofar as could be determined. The lesions disappeared just as rapidly with arsphenamin and the salicylate as when all three were administered; of course, lesions in some animals disappeared more rapidly than in others, but well-marked variations in individual rabbits did not permit the drawing of finer distinctions and deductions.

Influence of Iodids upon the Treatment of Chronic Rabbit Syphilis with Arsphenamin and Mercury.—Additional experiments were conducted to obtain more definite data upon the curative activity of iodids in chronic syphilis of rabbits when administered with arsphenamin intravenously, salicylate of mercury intramuscularly and mercurial ointment by inunction. Sodium iodid was selected because it is less toxic than potassium iodid.

The intravenous injection of arsphenamin in alkaline solution in dose of 0.008 gm. per kilogram (equivalent to about 0.5 gm. per 130 pounds) once a week for five weeks yielded approximately 60 per cent. of cures in the sense of complete disappearance of the external lesions of syphilis and sterilization of the lymph-glands. When injected along with the

daily administration of sodium iodid by mouth in dose of 0.03 gm. per kilogram, equivalent to 1.8 gm. or 30 grains per 130 pounds, the number of cures was almost the same.

The intramuscular injection of 0.001 gm. of the salicylate of mercury per kilogram, equivalent to about 0.06 gm. or 1 grain per 130 pounds, once a week for five weeks did not yield complete cures; the external lesions improved, but in some instances did not entirely disappear and the lymph-glands were not sterilized. When sodium iodid was given daily at the same time by oral administration in dose of 0.03 gm. per kilogram (equivalent to about 1.8 gm. or 30 grains per 130 pounds, complete cures likewise did not occur, but viewing the group of animals as a whole, the lesions disappeared more rapidly and more animals showed a complete disappearance of all external lesions, than occurred with the group treated alone with the salicylate of mercury.

The daily inunction of 0.06 gm. of 30 per cent. blue ointment (*massa hydrargyri*) per kilogram for 30 treatments, equivalent to about 3.6 gm. or one drahm per 130 pounds, cured approximately 20 per cent. of animals. In all instances the external lesions disappeared with sterilization of the lymph-glands in 20 per cent. The effects observed with these daily inunctions over a period of five weeks were more striking than in the group treated with the intramuscular injections of salicylate of mercury once a week for five weeks, described above.

When sodium iodid was given at the same time in dose of 0.03 gm. per kilogram by oral administration, equivalent to 1.8 gm. or 30 grains per 130 pounds, the percentage of cures was approximately the same. But a comparison of the two groups clinically from week to week showed conclusively that the lesions improved and finally disappeared more promptly among the animals receiving the iodid, although the percentage of animals showing complete sterilization of the lymph-glands was the same in both series.

The evidence of these animal experiments was confirmatory, therefore, of clinical experience, showing that the iodids exert a curative activity in chronic syphilis. The effects were about the same with oral and intravenous injections due, probably, to the rapid absorption of the iodids from the alimentary canal.

Whether the treatment of syphilis with arsphenamin or a mercurial compound and an iodid constitutes an example of combination therapy in the chemotherapeutic sense is uncertain; at the present time the larger part of the curative activity of the iodids is commonly ascribed to their effects upon the ferment-antiferment balance in the blood and tissues, the iodin serving to bind the unsaturated fatty acids and thereby releasing and activating tryptic ferments with the digestion and removal of inflammatory exudates and tissues. If this were the sole activity of the iodids as administered in the treatment of syphilis, their simultaneous use with arsphenamin, neoarsphenamin, mercury or bismuth would not constitute a form of combination therapy in the chemotherapeutic sense. However, it is possible that the iodid likewise exerts a feeble degree of spirocheticidal activity or increases the spirocheticidal activity of the arsenical, mercurial or bismuth compounds and, if the latter were the case, the curative activity of the iodids in syphilis would be due to a combination of effects, one of which would constitute an example of combination chemotherapy.

Advantage and Disadvantges of Combination Therapy in the Treatment of Human Syphilis.—The subject of combination therapy in syphilis is therefore, one of importance in the treatment of this disease. There are relatively few physicians today willing to treat cases exclusively with arsphenamin or its substitutes or with mercury or bismuth alone unless absolutely demanded by peculiar circumstances, as hypersensitiveness to one or more of these compounds. The great majority prefer to follow courses of arsphenamin or one of its substitutes with courses of mercury and the iodids or with bismuth and the iodids. This, however, is not combination therapy as I wish to discuss the subject here; rather I refer to the administration of two or more compounds at the same time either by administering them separately or in mixtures. Probably the oldest and best known type of combination therapy in syphilis is the mixture of bichlorid of mercury and potassium iodid in some suitable vehicle like syrup or sarsaparilla.

Not infrequently chronic syphilis is treated by intravenous injections of arsphenamin or neoarsphenamin combined with mercury by inunction and iodids by mouth; this is probably one form of combination therapy. Quite a number of physicians, however, hesitate to adopt such a method in fear of toxic effects and especially injury of the kidneys by mercury or of the liver by arsphenamin, thereby interfering with elimination and increasing the

chances of producing such serious untoward effects as dermatitis, hepatitis, and nephritis. Wechselmann is largely responsible for instilling this fear into the profession, but he has overemphasized the danger in his desire to blame the accidents of arsphenamin therapy upon mercury rather than upon arsphenamin itself. On the other hand, I do not wish to underestimate the danger; it is reasonable to assume that the simultaneous administration of two compounds capable of producing toxic tissue reactions, like arsphenamin or one of its substitutes along with mercury or bismuth, are more likely to produce toxic effects than any one of these compounds alone; but I believe that with due care in regards to dosage and administration that combination therapy is applicable to the majority of cases without increasing toxic effects and with much better therapeutic results.

Insofar as one may judge by the rapidity of disappearance of spirochetes from human chancres and mucous patches and healing of these lesions, I have not been able to satisfy myself that mixtures of neoarsphenamin and mercury are better than the arsenical alone, although there are numerous reports in the literature indicating that others have found this to be the case. In chronic syphilis, however, I am convinced that much is to be gained in the treatment of many cases by the administration of an arsenical along with mercury or bismuth and with an iodid at the same time.

Linsser's Method of Combination Therapy in Syphilis.—In 1919 Linsser[3] advocated treatment with mixtures of neoarsphenamin and bichlorid of mercury by intravenous injection. His method consists in dissolving 0.45 to 0.6 gm. of neoarsphenamin in 5 c.c. of sterile distilled water and adding 1 to 2 c.c. of a 1:100 solution of bichlorid in water corresponding to 0.01 to 0.02 gm. or $\frac{1}{6}$ to $\frac{1}{3}$ grains; if well borne he later adds as much as 6 c.c. of the bichlorid solution which corresponds to 0.06 gm. or 1 grain, a rather large dose by intravenous injection. These injections are given every 3 to 5 days for courses of 4 to 10 injections.

As soon as the two solutions are brought together in a syringe the color is changed to a very dark greenish-black due to the precipitation of the mercury, the chemistry having been recently discussed by Kolle.[4] It is a most unsightly mixture and one naturally hesitates to inject it. Furthermore, it is difficult to see the "flash" of blood in the syringe as an indication that the vein has been entered and a series of injections tends to produce phlebitis; there are therefore, distinct disadvantages to the method.

Since Linsser published his results, quite a large literature has accumulated upon the use of the method in Germany among which may be mentioned the publications by Gutmann,[5] Holzhauser,[6] Lowenstein,[7] Zirn,[8] Johnson,[9] Oelze,[10] Eicke and Rose,[11] Schmidt,[12] Ebel,[13] Brann[14] and others who claim that the results are generally superior in all stages of syphilis to those observed with similar doses of neoarsphenamin alone and that toxic effects are not enhanced. Bruck[15] however, has advocated the use of novasurol, a double salt of sodium hydroxy-mercury-chloro-phenoxyacetate and diethyl malonylurea, containing 33.9 per cent. mercury, as a substitute for mercuric chlorid, because dissociation is less rapid, with the result that the solutions do not become more than slightly opalescent and yellowish-green within a minute, which permits one to see the flash of blood in the syringe, and because phlebitis is not so likely to be produced. Schonfeld,[16] Biederstedt,[17] Issel,[18] Krebs[19] and others have reported favorable results with this combination as likewise Boas and Pontoppidan,[20] Krug,[21] Oelze,[22] Bab[23] and others with "cyarsal," the potassium salt of a nuclear mercurated oxybenzoic acid. Rebandi[24] reports favorably upon the use of "neobiol," an organic combination of bismuth and arsenic in a benzol ring, in dose of 0.1 to 0.3 gm. by

intravenous injection. I have employed mixtures of neoarsphenamin and mercurophen; also neoarsphenamin and flumerin, the technic being described in Chapter LXII.

There is, therefore, quite a large and favorable literature upon combination therapy in syphilis and I believe the subject is worthy of more consideration than it has received in this country. A great disadvantage is the summation of toxic effects, but, as I may affirm from clinical experience, this is more theoretical and fanciful than real. It is true that each case of syphilis must be decided upon individual conditions; for example, I would not consider combination therapy in the presence of kidney and liver disorders in fear of accidents due to faulty elimination. Even in the treatment of acute early syphilis, I believe something better is to be gained by giving one of the arsenicals intravenously while mercury is given by inunction than when the arsenicals alone are given; if inunctions are not convenient or possible I do not hesitate to inject the salicylate or succinimid intramuscularly. If these are objected to, I combine neoarsphenamin with mercurophen or flumerin in the same syringe and inject intravenously, as described in Chapter LXII. In the treatment of chronic syphilis I believe the indications and results are even better and especially in "Wassermann-fast" cases, due apparently to acquired arsenic resistance. In cases selected with due care, I have not seen any ill effects and belive that the results are better with shorter combination courses than with the usual long drawn out courses of arsphenamin or one of its substitutes followed by mercury. But this is too important a subject to be discussed with a few words and will be considered with more detail in chapters devoted to the treatment of chronic syphilis; here I merely wish to record my opinion that combination therapy is worthy of serious consideration for improving therapeutic results and especially in chronic syphilis, and with due care in the selection of cases, drugs, doses, intervals of administration and length of "courses" it is a harmless method from the standpoint of untoward reactions.

Stokes,[25] in writing of the combination of mercury with arsphenamin in the treatment of syphilis, states that "to secure the maximum combination of benefits, with the minimum of defects from both drugs, I believe it is essential, especially in early cases, to use them simultaneously rather than alternately. Prolonged observation of the effect of this combination has made me believe them actually synergistic in effect, and without permanent damaging effect on the excretory mechanism." Stokes, however, is against the use of intramuscular injections of insoluble salts of mercury, because the formation of mercurial depots of unknown capacity in the tissues of patients of unknown resistance and tolerance in an adventure in speculative therapy that his experience with the kidneys in syphilis will not countenance.

Limitations of Arsphenamin and Its Substitutes Alone in the Treatment of Syphilis.—Certainly the treatment of syphilis with arsphenamin or its substitutes alone has proven unsatisfactory. The hopes originally entertained of the curative action of arsphenamin alone in syphilis have not been realized and especially in chronic syphilis; undoubtedly, many cases treated in the early stages with arsphenamin and neoarsphenamin alone are being cured and the drugs have likewise proven efficacious in the prophylaxis of syphilis, but in chronic syphilis the tendency is always to include mercury in treatment. Furthermore the intensive use of arsphenamin alone is more dangerous from the standpoint of toxic reactions than milder dosage made possible by combination therapy; it is also more likely to produce neural or other Jarisch-Herxheimer reactions than mercury and the latter should always

preceed as the advance guard of therapeutic attack in the treatment of neurosyphilis and chronic syphilis in general.

Limitations of Mercury, Bismuth and the Iodids Alone in the Treatment of Syphilis.—But if it is unwise to depend upon arsphenamin and its substitutes alone for the treatment of any but the earliest cases of syphilis, the same may be said of mercury. In acute early syphilis it is apparently not possible to give enough mercury to produce such prompt spirocheticidal effects as to prevent considerable dissemination of the spirochetes; the lesions are dissipated but not as rapidly as by adequate doses of arsphenamin. To-day we should not be satisfied with the results secured by Fournier in the days of treatment with mercury and iodids alone since it is entirely likely that the incidence of tertiary syphilis was higher than he thought in view of the advances made during the past twenty years in the serological and clinical diagnosis of chronic syphilis and especially of the central nervous system. Undoubtedly good and even splendid results were secured by Fournier and other syphilologists of experience with mercury in the pre-arsphenamin days, but not as good as they believed although mercury is unquestionably curative in syphilis, in the strict sense of the term and not merely a simple "obliterator of lesions" or a "whitewasher" of symptoms.

To treat syphilis with the iodids alone is out of the question, except in those occasional cases of tertiary syphilis of aged individuals to whom relief from a gumma is all that can be hoped for without involving the possibility of effecting a cure; likewise in the treatment of cases of tertiary syphilis to whom mercury, bismuth and the organic arsenicals cannot be given because of a general break down of the cardiovascular and eliminative organs, but who are urgently in need of relief from a threatening gummatous lesion. Neither are we justified in relying upon mercury alone or bismuth alone if it is possible to give one of the organic arsenicals in addition. In short, best results for the majority of cases are secured by a judicious combination of these remedies. It is not a question of arsphenamin *versus* mercury or the reverse, according to one's prejudices; both classes of compounds are capable of doing both harm and good. What is needed is a good working knowledge of both including bismuth and the iodids, so that the patient rather than the disease may be treated in the manner best suited for each individual case.

CHAPTER XXXI

CHEMOTHERAPY OF FRAMBESIA TROPICA, RELAPSING FEVER, RAT-BITE FEVER, VINCENT'S ANGINA, GINGIVITIS, PULMONARY SPIROCHETOSIS, AND OTHER SPIROCHETIC AND LEPTOSPIRA DISEASES OF MAN AND THE LOWER ANIMALS

As reviewed in preceding chapters, arsphenamin and neoarsphenamin have been found very efficacious remedies for various spirochetic infections besides syphilis and notably in frambesia tropica and relapsing fever. These compounds and the organic arsenicals, as a group, are general spirocheticides and have been found valuable in the treatment the various spirochetic infections of man and the lower animals. Indeed, as in frambesia, the results have been sometimes more brilliant and satisfactory than those obtained in syphilis, and the purpose of the present chapter is to discuss the specific therapy of these various non-syphilitic spirochetic infections of human beings.

Chemotherapy of Frambesia Tropica.—Shortly after the discovery of salvarsan (arsphenamin), Nichols[1] found that it had a remarkable curative effect in the treatment of rabbits experimentally infected with the disease (*Sp. pertenuis*), and almost simultaneously Strong[2] and Castellani[3] observed extremely satisfactory results in the treatment of human cases, the former observing in the treatment of twenty-five cases with single injections, that the granulomatous lesions began to recede in three to four days and generally disappeared entirely in ten to twenty days. These results were soon confirmed and, indeed, the curative effects of arsphenamin and neoarsphenamin have been proven so remarkable that many physicians have expressed the opinion that Ehrlich's dream and hope of a *therapia sterilisans magna*, the complete cure of a disease by a single injection of drug, has been realized in many cases of this infection.

As recently stated by Fox,[4] frambesia tropica does not occur in the United States except in imported and isolated instances at seaports, despite the fact of its prevalence in the West Indies. Goodman,[5] Schamberg and Klauder[6] and others have reported isolated cases in which the lesions were rapidly dissipated and the positive Wassermann reactions reduced to negativity by intravenous injections of neoarsphenamin. The disease, however, is prevalent in the West Indies, Central America, northern part of South America, Africa, Philippines, Guam, Porto Rico, etc., and the wonder is that it is not more frequently seen in the United States, although it is said never to occur in the mountains and cold districts and rarely above an elevation of 800 feet.

The disease is known by various names in different localities, such as "yaws" in the English colonies; "pian," in the French colonies; "bolobo" in the Belgian Congo and "bouba" or "boubas," in the Spanish domains. By some physicians it is believed to be a tropical form of syphilis, but it is generally regarded at present as a separate disease due to a closely related spirochete. The infection is not transmitted by sexual congress in more than 1 per cent. of cases and is not transmissible to the offspring. The primary lesion, "mother yaw" or "madre buba," generally occurs on the extremities and infection prob-

ably requires a break in the epithelium by trauma or the bites of insects and especially by flies. The generalized eruption follows in a few months and is characterized by widespread granulomatous lesions which may undergo ulceration with a great deal of deformity. Smears of these lesions generally show an enormous number of spirochetes, which is in sharp contrast to the few spirochetes in secondary syphilitic skin lesions.

In the majority of cases, the lesions of frambesia appear to be confined to the skin, mucous membranes and bones, and this probably accounts for the fact that it is not transmissible from parents to children, since the generative organs do not become involved nor do periods of spirochetemia develop, although Harper[7] claims that it has produced abortions and miscarriages among the women of the Fiji islands, where almost every one contracts the disease and where treatment with arsphenamin and neoarsphenamin has yielded brilliant results. The internal viscera, however, do not always escape and most physicians experienced in the disease believe that a tertiary stage may develop with lesions in the internal organs. Castellani regards "*gangosa*," or rhinopharyngitis mutilans, an ulcerative condition of the palate, nose, pharynx, and skin surfaces of the body, a probable late sequela of frambesia, which slowly spreads to the nose and larynx, destroying cartilage and bone, and causing much deformity. Kerr[8] believes it is either a tertiary frambesial or syphilitic lesion. Even the central nervous system may be apparently involved in exceptional cases with spinal fluid changes and symptoms resembling locomotor ataxia and other syndromes resembling syphilitic infection of these tissues, as reported by Chatellier,[9] Hunt and Johnson,[10] and others. It is possible, however, that in some of these cases syphilis was present. Indeed, Parham[11] and not a few of the Army surgeons, believe that frambesia is a form of syphilis, although, as stated above, the weight of opinion is against this view. At any rate, the lesions are largely cutaneous and this accounts for the rapidity of cure just as the skin lesions of syphilis are usually rapidly cured by treatment with arsphenamin and neoarsphenamin. Ulcerated lesions, however, may require more prolonged treatment as originally advised by Strong, since the spirochetes may be well enmeshed in inflammatory fibrous tissue and exudates. *Sp. pertenuis*, however, does not produce the same degree of perivascular exudations and thickening of blood-vessel walls as does *Sp. pallida*, and this circumstance greatly aids in the cure of the disease by arsphenamin and neoarsphenamin.

From the standpoint of specific therapy it may be stated that mercury is almost without effect. Potassium iodid is helpful in deep seated and chronic lesions, especially those involving the bones, but it is slow in action and but feebly spirocheticidal, although in combination with tartar emetic it may yield good results. Castellani[12] has used a combination of this kind according to the following formula, as a substitute for arsphenamin treatment:

Tartar emetic	gr. i
Potass. iodid	℥i
Sod. salicyl	gr. x
Sod. bicarbon	gr. xv
Glycerin	f℥ ii
Water	q.s. f℥i

This dose (one ounce diluted with three ounces of water) is given to adults three times a day, children receiving one half as much, for ten to fifteen days; it is then discontinued for one week and repeated again for ten to fifteen days. Guerro and his colleagues,[13] as well as Viswalingham[14] and others, have reported good results with this therapy.

But by far the best results have been observed with arsphenamin and neoarsphenamin, as shown by a host of reports, among which may be mentioned, in addition to those already cited, those by Flu,[15] Alston,[16] Koch,[17] Scherschmidt,[18] Cockin,[19] Brochard,[20] Baetz,[21] Reed,[22] Girling,[23] McDonald,[24] Bergen,[25] de Boissiere[26] and Tournier.[27] These reports, from different parts of the world and embracing the treatment of thousands of cases, are without exception most favorable to the treatment of the disease with arsphenamin and its substitutes. In the earlier work, intramuscular injections were given, but these were soon replaced by intravenous injections and the reports on treatment with different brands of neoarsphenamin appear to be as good and satisfactory as with different brands of arsphenamin. One of the most

recent reports is by Moss and Bigelow,[28] of a commission sent by the School of Tropical Medicine of Harvard University to the Dominican Republic. Of 362 cases treated with a *single* intravenous injection of 0.6 gm. neoarsphenamin:

20 per cent. were cured or practically cured.
59 per cent. were improved.
21 per cent. were not improved.

But cases receiving three or four injections were cured or improved in the majority of cases, as shown in the following results with 39 cases:

44 per cent. cured or practically cured.
54 per cent. improved.
2 per cent. not improved.

Recently Paterson[28a] has reported favorably upon the results of treatment with bismuth, the salt employed being sodium and potassium bismuth-tartrate in dose of 3 grains for the adult injected intramuscularly in 2 c.c. of sterile water. Probably the oily suspensions would prove better from the standpoint of producing less local reaction and pain and doubtless a series of injections at intervals of 5 to 7 days are required; I suggest the following plan of treatment for this disease:

1. The same general precautions against toxic reactions are required as in the treatment of syphilis. When conditions permit, the urine should be examined and the Wassermann reaction conducted.

2. Four to six weekly injections of arsphenamin in dose of 0.4 to 0.6 gm., or neoarsphenamin in dose of 0.6 to 0.9 gm., for adults by intravenous injection; children to receive smaller amounts proportionate to weight. If the lesions are ulcerative and involving bone, potassium iodid may be given at the same time by ingestion.

Sulpharsphenamin has not yet been reported upon in this disease, but in consideration of the excellent results observed in syphilis, and since it may be given by subcutaneous and intramuscular injection which are always easier than intravenous injections in the tropics amidst the unhygienic and difficult conditions surrounding centers for the treatment of the disease, I believe it is worthy of trial in dose of 0.6 gm. (0.3 gm. in each buttock) once a week for at least four to six weeks.

If conditions are such that multiple injections cannot be given, I would not hesitate to inject adults in good general condition with 0.8 gm. of arsphenamin or 1 gm. of neoarsphenamin by intravenous injection, or 0.6 g. of sulpharsphenamin by intramuscular injection (0.3 gm. in each buttock), and follow this up if possible by the internal administration of Castellani's mixture.

3. After the course of injections, a rest of one month may follow when the Wassermann test should be repeated. If a positive reaction is observed, an additional series of injections should be given.

It is not necessary to examine the spinal fluid, since infection of the central nervous system occurs so rarely, unless there are clinical signs of involvement.

The criterion of cure has been the disappearance of the outward manifestations of the disease and since visceral involvement is exceptional and transmission to offspring known not to occur, this would appear sufficient. But when conditions permit, the Wassermann test by a sensitive method should be included and specific treatment continued until a state of negativity is obtained over a period of at least one year.

Chemotherapy of Relapsing or Recurrent Fever.—Since a great deal of the fundamental chemotherapeutic investigations by Ehrlich and Hata were done

with mice infected with *Sp. obermeieri*, it is no wonder that human beings suffering with relapsing or recurrent fever were among the very first to benefit from the discovery of salvarsan (arsphenamin). Apparently all species of the spirochete of relapsing fever are highly susceptible to arsphenamin and neoarsphenamin, since complete cures have been recorded from single injections in the treatment of infections with *Sp. obermeieri* (European relapsing fever), *Sp. duttoni* and *Sp. kochi* (African relapsing fever), *Sp. carteri* (relapsing fever of India), *Sp. barbera* (relapsing fever of northern Africa) and *Sp. novyi* (American relapsing fever). The disease, therefore, is widely distributed and isolated cases have been reported in the United States by Briggs[29] and others.

Following encouraging laboratory experiments with atoxyl and other pentavalent arsenicals, Glaubermann[30] employed atoxyl in the treatment of human infections and Iversen[31] and others used arsacetin; but owing to the great superiority of arsphenamin and neoarsphenamin from the standpoint of lesser toxicity and greater spirocheticidal effects, these drugs are no longer employed, although Mante[32] has used arrhenal and Portocalis[33] has used galyl with some success.

Iversen[34] was first to report upon the arsphenamin treatment of human cases of the disease and in a series of 55 observed an apparent cure in 92 per cent. following the intramuscular injection of a single dose of 0.2 to 0.3 gm. of salvarsan (arsphenamin). Relapses occurred in 4 or 8 per cent. of the cases and one cured case was later re-infected. Iversen noted a disappearance of the spirochetes from the blood in four to ten hours after injection and in the majority a complete sterilization resulted, fulfilling Ehrlich's prediction of successful *therapie magna sterilisans*. At the same time, Bitter and Dreyer reported the successful treatment of thirteen cases with arsphenamin and since then Smirnoff,[35] Iversen,[36] Jarno,[37] Robledo,[38] Manson and Thornton,[39] Saceghem,[40] Prussian,[41] Lorentz,[42] Zeller[43] and others have reported excellent results with arsphenamin and neoarsphenamin, although Peacock[44] claims that arsphenamin frequently fails to cure the disease. As stated in Chapter LXXVI individuals with paresis and other types of neurosyphilis have been treated by artificial inoculation with relapsing fever as a substitute for malarial inoculation and these infections are said to be promptly cured by the administration of arsphenamin or neoarsphenamin.

For treatment either arsphenamin or neoarsphenamin may be employed by intravenous injection. Sulpharsphenamin has not yet been reported upon, although I have found it curative by subcutaneous, intramuscular and intravenous injection in mice experimentally infected with *Sp. novyi*. Very probably it will find a useful place in the treatment of relapsing fever in Africa and other localities where subcutaneous or intramuscular injections can be more readily given on a larger scale than intravenous injections. The following method of treatment may be employed:

1. The intravenous injection of 0.6 gm. arsphenamin or 0.9 gm. neoarsphenamin during the attack when spirochetes are present in the blood. Best results have been observed when treatment was given while the fever was mounting rather than during the periods of intermission. If the patient is first seen during the afebrile period, it is advised to wait until a paroxysm is developed before administering the drug.

2. The patient should be kept under observation, with frequent examinations of the blood, and given another injection if parasites are found or a paroxysm occurs.

3. According to most observers only one or two doses are required, but in long standing infections a series of injections may be necessary. Since the spirochetes may be rendered "arsenic-fast," it is well to treat with large doses as required, rather than small doses at frequent and close intervals.

Chemotherapy of Rat-bite Fever.—That the bite of an animal, especially the rat, may cause infection in man with different microörganisms is obvious to anyone who makes a careful survey of the literature of diseases produced by bites of the rat, mouse, cat, dog, ferret, weasel, etc. In Japan a paroxys-

mal febrile infection of the relapsing type frequently follows the bite of rats, and similar cases have been observed in the United States and Europe. The wound heals readily, but after a variable incubation period of a few days to a month it becomes inflamed and painful. Lymphangitis and adenitis develop and are quickly followed by symptoms of systemic infection ushered in by a chill and rapid rise in temperature. There are extreme prostration, severe generalized muscular pain, headache, weakness, and loss of appetite. Stupor, delirium, and even coma may supervene. There is muscular tenderness and rigidity and the tendon reflexes are frequently exaggerated. A characteristic exanthem of bluish red, erythematous, sharply marginated macules appear of various sizes and of general distribution. After five to nine days the temperature falls by crisis accompanied by a profuse sweat and all symptoms subside. The disease then assumes the relapsing type with paroxysms occurring at fairly regular intervals, usually about once a week. The course may vary from one to three months or even longer. Gradually the relapses become less frequent and less severe and the disease often terminates with an abortive paroxysm. The more important complications are nephritis, severe anemia, and emaciation. About 10 per cent. of the cases terminate fatally, usually during the first febrile period, occasionally later from nephritis or exhaustion. The Wassermann reactions have been reported as uniformly negative.

That rat-bite fever is an infectious disease dependent upon the introduction of a specific organism or virus at the site of the bite seems highly probable. There has been no definite evidence presented to show that the rat inflicting the bite was in any way diseased or other than a normal rat. In view of this negative evidence it does not seem improbable that the etiological agent is simply a saprophyte in the mouth of the rat. Individual susceptibility seems to play a definite part in the contraction of the disease, as instances are recorded in which the second of two people bitten by the same rat has been the only one to develop rat-bite fever. Nixon[45] has reported a case similar to rat-bite fever following the bite of a ferret, and Schottmuller[46] a case incident on the bite of a South African squirrel. That the etiological factor in such cases is closely related to that occurring in rat-bite fever is possible. I may state, however, that the bite of the white rat in this country is apparently without danger of producing the disease; at least, my assistants and I have been bitten innumerable times during the past ten years but in no instance have there followed the febrile attacks of rat-bite fever.

Various microörganisms have been regarded as causing the disease, the etiology being still uncertain, and it is highly probable that at least two forms of the disease may exist, namely, a spirochetic type due to *Spirochæta morsus muris*, discovered by Futaki, Takaki, Taniguchie and Osumi[47] and especially prevalent in Japan, and a type due to *Streptothrix muris ratti*, discovered by Schottmüller, and found in Europe and the United States by Blake,[48] Tunnicliff[49] and Tileston;[50] Arkin,[51] in a recent review of the literature on the disease, believes that the spirochete is to be regarded as the primary etiologic agent.

Arsphenamin, first employed by Hata[52] in 1912 in the treatment of eight cases of the disease, is commonly regarded as the best available remedy, but not necessarily as a specific. Bergamini,[53] Tileston,[54] Delal,[55] Surveyor,[56] Powell,[57] Solly[58] and Burton-Fanning[59] have reported successful treatment with arsphenamin and neoarsphenamin, and two additional cases have been recently reported by O'Leary,[60] who has especially described the skin lesions of the disease, successfully treated with arsphenamin. Borelli[61] states that mercury has curative activity, but this statement has not been confirmed, arsphenamin and neoarsphenamin being the remedies of choice.

If the wound is seen immediately it should be cauterized and this procedure is stated to prevent the disease if applied within an hour. It may be possible that the thorough application of 33⅓-per cent. calomel ointment will likewise act as a prophylactic, although I do not know of any instance in which this has been tried. From 3 to 6 injections of arsphenamin or neoarsphenamin are usually given at five to seven day intervals, followed by one or

two more after the subsidence of all symptoms, to prevent a relapse. Following the first injection, a Herxheimer-like flare-up may occur, with elevation of temperature and transitory accentuation of the lesions.

Chemotherapy of Vincent's Angina.—The cause of Vincent's angina is now quite universally accepted as being *B. fusiformis* and a spirochete designated as *Sp. vincenti.* Whether the bacillus is a form of the spirochete, or a separate organism, cannot be stated; nor is it certain that the spirochete is a separate entity, since it may be one of the several species to be found about the teeth and gums. Spirochetes and fusiform-like bacilli are quite commonly found in the tartar deposits and decayed food debris of the teeth, and, while ordinarily saprophytic, are apparently capable of exciting inflammatory changes and tissue necrosis, especially when the resistance of the tissues is lowered by gingivitis and stomatitis, due to gastro-intestinal disturbances from scorbutus and other dietary and metabolic errors, to the elimination of mercury or to plain neglect of oral hygiene with tremendous proliferation of streptococci, various bacteria, yeasts and fungi known as oral sepsis. In other words, we may have low grade inflammatory changes in the gums apparently caused by spirochetes, fusiform bacilli and other organisms; in exceptional instances, and especially in children, the fusiform bacilli and spirochetes are capable of exciting an acute ulcero-membranous infection of the tonsils and uvula, sometimes involving the gums and sides of the tongue, and accompanied by adenitis, designated as *Plaut-Vincent's angina.* The disease is commonly mistaken for diphtheria and is infectious, epidemics sometimes occurring in institutions and among soldiers. Thus Bouty,[62] Campbell and Dyas,[63] Tixier and Tobe[64] and others have described small epidemics in the recent World War in which the incidence among soldiers has been as high as 23 per cent. The infection may also extend to the nasal cavities and even to the accessory sinuses: I have seen a fatal case in the child of four years due to infection of the antrum of Highmore on the left side with extension into the orbit. These nasal infections, however, should not be mistaken for Castellani's spirochetic rhino-pharyngitis due to *Spiroschaudinnia minuta*, which is a rare disease and to the best of my knowledge not reported so far in America.

The bacteriological diagnosis of Vincent's angina is not ordinarily a difficult matter and is made by the examination of smears and not by cultures. Smears may be stained with hot diluted carbol fuchsin (1:5) for a few seconds, which serves to bring out the spirochetes and curved, banana-shaped, granular, fusiform bacilli.

Various local applications have been advocated from time to time for the treatment of this infection, among which may be mentioned applications of solutions of copper sulphate, potassium chlorate, iodin, chromic acid (2-per cent.), etc.; also powdered methylene-blue, Dakin's solution, acriflavine, etc. Arsphenamin and neoarsphenamin, however, have yielded particularly good results and especially by local application. As stated in Chapter XXVIII, both arsphenamin and neoarsphenamin are undoubtedly spirocheticidal by local contact with *Sp. pallida* and I have found both drugs capable of destroying the mouth spirochetes as well, when brought in contact with them in the secretions. Whether or not these compounds are destructive for the fusiform bacillus cannot be stated.

Intravenous injections of arsphenamin and neoarsphenamin do not ordinarily influence the spirochetes of the mouth. I have found, for example, that fuso-spirillar gingivitis in syphilitic individuals under treatment with these compounds, is apparently not influenced, but in severe and extensive *Vincent's angina,* intravenous injections are apparently efficacious because

of the deep seated lesions, as indicated by the reports of Tixier and Tobe, Greene,[65] Spano,[66] Morgan,[67] Hirsch,[68] Bruggeman[69] and others; I have also found them efficacious in the treatment of Vincent's infections of the bronchi. Barenberg and Bloomberg[70] have recently described the successful treatment of Vincent's angina of children with one or two intramuscular injections of sulpharsphenamin combined with local applications of the drug, and practically all of the previous mentioned writers, in addition to Reckford and Baker,[71] Citron,[72] Amsden,[73] Gougerot, Goullier and Vaslin,[74] Zilz,[75] Voss,[76] Achard,[77] Renon and Desbouis,[78] Niglot and Levy[79] Rolleston[80] and others, have reported successful results from treatment with local applications of arsphenamin or neoarsphenamin. For the treatment of fuso-spirochetal ulcero-membranous angina these compounds may be regarded as specifics, insofar, at least, as concerns the part played by spirochetes. Recently Driscoll[81] and Vonderlehr[82] have reported excellent results in the treatment of Vincent's angina with intravenous injection of 1 per cent. solutions of tartar emetic in dose of 5 to 10 c.c. repeated if necessary every two to three days, severe cases requiring about six injections. Driscoll states that he has also employed this drug with success in the treatment of "trench mouth."

The specific treatment of Vincent's angina may be summarized somewhat as follows:

1. In severe cases neoarsphenamin may be injected intravenously or sulpharsphenamin intramuscularly, the doses for adults being 0.9 and 0.4 gm. respectively, children receiving less in proportion to body weight. Two to four injections at intervals of 4 or 5 days may be required to check the disease, subsequent treatment being by local applications. If these fail it may be well to try tartar emetic by intravenous injection in dose of 5 to 10 c.c. of a sterile 1 per cent. solution.

2. Local applications are always required in addition, and for the usual and milder infections may alone suffice for treatment. The method of local treatment has been described in Chapter VIII, but a choice may be made of any of the following preparations: (*a*) 2-per cent. solutions of arsphenamin or 4-per cent. solutions of neoarsphenamin in 50-per cent. glycerin; (*b*) 10-per cent. suspensions of arsphenamin or neoarsphenamin in pure glycerin; (*c*) the powder of either drug applied by swabs dipped in glycerin.

It is necessary to apply the chosen preparation very thoroughly, and after preliminary cleansing by means of swabbings and gargling with diluted *liquor antisepticus* or any other suitable antiseptic solution. The preparations may gradually turn darker in color, owing to oxidation, but this does no harm until a very dark green color results in which case oxidation has probably proceeded to the stage when the preparation loses in spirocheticidal activity and should be renewed. My favorite preparations are the 2- to 4-per cent. solutions in 50-per cent. glycerin, but an equally good method is to take a 0.6 gm. tube of neoarsphenamin, file off the tip, add 6 c.c. of glycerin, mix well to secure an even suspension and apply two or three times a day with cotton applicators until evidences of healing are apparent, when one or two applications per day may suffice until healing is complete. In addition to these applications it is sometimes advisable to apply a 2-per cent. solution of chromic acid, once or twice a day by means of an atomizer.

Chemotherapy of Gingivitis or Pyorrhea Alveolaris.—The importance of gingival infections is universally recognized by both dental and medical professions, not only in relation to the purely local effects in the mouth, but also in relation to focal infection or the development of general pathological conditions as anemia, acute and chronic arthritis, neuritis, vascular, myocardial and renal degenerations and inflammations.

In the majority of cases the disease apparently begins on the surface of the gums (*a gingivitis*), infection being aided by mechanical injury of the tissues and neglect of oral hygiene. When neglected, the inflammation advances along the root of the tooth into the alveolus, destroying the tissues of the peridental ligaments and producing thereby a series of suppurative cavities or pyorrheal pockets, exposing the cementum and finally causing its absorption (*chronic suppurative pericementitis*) with suppuration, necrosis and absorption of the alveolar processes (*chronic suppurative alveolitis*), resulting in the loosening and loss of teeth.

These changes may be and usually are, associated with abscesses at the roots of one or more teeth (apical abscesses), although these infections are usually caused by direct exposure of the root canals by cavities or, in the absence of these, possibly, in some cases, by infection of the periapical tissues by organisms brought to the parts by the blood or lymphatic channels.

The mouth constantly harbors various bacteria, fungi and some protozoa, notably *Endameba buccalis* and different varieties of spirochetes. Among the bacteria, staphylococci, streptococci, pneumococci and *B. acidophilus* are usually to be found and all of these are capable of inducing low grade inflammatory changes when their invasion into the tissues of the gums is aided by abrasions due to picking and brushing of the teeth, by accumulations of tartar or by minute injuries from other causes; colonies of bacteria and molds growing between the teeth in tartar deposits may produce sufficient amounts of toxins to cause superficial erosions and thereby aid infection of the deeper tissues. As shown by Smith and Barrett, *Endameba buccalis* may be present and by means of its migratory and digging movements, carry bacterial and spirochetic infection into the deeper tissues. No doubt diet deficiency and various systemic and metabolic disturbances are to be regarded as etiological agents of importance in the production of gingivitis, but sooner or later bacterial or spiro-fusillar infections become factors of secondary importance and in some cases at least, may be indeed the primary cause. The chemotherapy of gingivitis is therefore, directed against this primary or secondary infection.

In all cases of chronic suppurative gingivitis bacterial infection may be said to play an important part. In many cases, however, examination shows such a preponderance of spirochetes, with or without fusiform bacilli, that these organisms are to be accepted as playing the major role in infection and especially in "trench mouth." Endamebas may be found in both bacterial and spirochetic types of the disease, but they are not to be considered a cause of the infection but important secondary invaders capable of carrying infection into the deeper tissues. Various molds and yeasts are usually found, but their importance has never been estimated and it is highly probable that they are of secondary importance.

The proper treatment of gingivitis or pyorrhea alveolaris, therefore, requires a bacteriological diagnosis for the purpose of determining whether the infection is purely *bacterial* (the usual normal or but slightly increased flora of spirochetes and molds being also present), or predominently *spirochetic* (some bacteria being always present). At the same time a search is made for endamebas, for if present in increased numbers, adequate measures for their destruction may be required. In the majority of cases these examinations disclose an increase of both bacteria and spirochetes and local treatment should be directed against both of these in addition to the usual surgical procedures. This differential bacteriological diagnosis may be made by the examination of simple smears of gingival material.

From the standpoint of chemotherapy it is necessary to approach the subject of treatment from that of specific chemical disinfection of the tissues by both the local and systemic administration of parasiticidal agents. Unquestionably the subject of local disinfection is the more important of the two; indeed, from the standpoint of systemic medication, only the possibility of influencing spiro-fusillar infections with intravenous injections of arsphenamin and its congeners, or of tartar emetic, as recommended by Driscoll[83] and mentioned above in the treatment of Vincent's angina, are worthy of consideration. Naturally a host of chemical agents have been proposed for the local disinfection of the gums and I have recently described the results of my bactericidal and spirocheticidal tests with a number of these in relation to the chemotherapy of gingivitis.[84]

I well realize that local disinfection of the gums is only a part of the required treatment but I believe that its importance and possibilities as an adjuvant to surgery, the administration of vaccines, etc., is worthy of closer attention. This would appear to be particularly true in the treatment of incipient cases as likewise in the nature of a "follow up" treatment to prevent relapses of the disease. I well realize that in severe cases with pyorrheal pockets involving the destruction of considerable peridental membrane and periosteum with absorption of considerable alveolar process, that surgery is especially indicated, but even in these the application of suitable disinfectants would appear to be useful as a form of adjuvant therapy.

But unquestionably the most important single factor in the chemotherapy of gingivitis, is frequency of application of the chosen disinfectant. When one remembers that within a few hours bacteria and spirochetes are capable of proliferating greatly and contaminating the treated tissues, it is apparent that frequent applications are indicated in the treatment of gingivitis, as is true of the local treatment of infections of the eyes, of wounds and other tissues and organs of the body. Indeed, I believe that failure in the treatment of gingivitis is due much more to this factor than to a lack of suitable disinfectants.

For the majority of cases of gingivitis local applications of a disinfectant will probably continue to be the usual practice insofar as chemotherapy is concerned. It is true that a large literature indicates that the intravenous injection of arsphenamin or neoarsphenamin or the intramuscular injection of sulpharsphenamin may prove helpful in the treatment of spiro-fusillar infections (Vincent's angina and "trench mouth") but these cases are only a small part of the total. I have observed many cases of spirochetic gingivitis among individuals who had received as many as twelve or more intravenous injections of arsphenamin or neoarsphenamin and it is my opinion that the intravenous administration of these anti-syphilitic arsenicals does not benefit gingivitis unless the gingival lesions are syphilitic or possibly a severe Vincent's infection.

Furthermore, the intravenous injection of tartar emetic in the treatment of spiro-fusillar gingivitis is still under trial and the subcutaneous injection of emetin hydrochlorid has not only failed to fulfill early expectations but is usually contraindicated by the slight importance to be attached to the presence of *Endameba buccalis* as likewise by reason of the possibility of disagreeable and even dangerous toxic reactions when adequate amounts are administered. Since stovarsol is apparently proving efficacious in the treatment of amebic dysentery it may be worthy of trial in the treatment of gingivitis, when so many amebae are found in the pyorrheal pus as to demand something for their destruction. Possibly the local application of solutions of this compound to the gums may be worthy of trial combined with the internal administration of 0.5 gm. in capsules two or three times a day for three to six days.

Certainly chemotherapy has nothing to offer in the way of systemic medication for the treatment of bacterial infections of the gums or for sterilizing the pus at the apex of a tooth. Even though the majority of organic and inorganic salts of mercury possess a high bactericidal and spirocheticidal activity *in vitro* and may be deposited or eliminated in the gums as a sulphid following internal administration, it is well known that this compound not only fails to influence the bacterial and spirochaetic flora of the gums but may actually aggravate the course of a gingival infection.

Local applications therefore, continue to be, for the present at least, of most importance in the disinfection of the gums. A host of substances have

been used but with the exception of the mercurial and silver salts and iodin, these are usually very low in parasiticidal activity although agreeable to the taste and otherwise elegant pharmaceutical preparations. Barrett and others have used local applications of 1 per cent. arsphenamin or 2 per cent. neoarsphenamin in the treatment of spirochetic gingivitis with some success, as would be expected because of the spirocheticidal activity of these compounds, but arsphenamin and neoarsphenamin are too low in bactericidal activity to be used alone in the majority of cases and I believe that mercurophen and metaphen are of more promise because of their higher spirocheticidal and bactericidal activity as well, presumably, of a high amebicidal activity. It is easily possible however, to use a mixture of arsphenamin or neoarsphenamin by taking into a syringe equal parts of a 1 to 2 per cent. solution of the former and a 1:500 stock solution of either mercurophen or metaphen. Mercuric chlorid and cyanid however, cannot be used in this way because of a precipitation of mercury.

But the method of application is of more importance. Preliminary cleansing and removal of tartar deposits with a general surgical overhauling are of prime importance. Pockets must be treated by the dentist and for this purpose I would suggest the instillation of 1:500 solutions of either mercurophen or metaphen alone or in combination with arsphenamin solution as compounds fulfilling acceptably the essential properties of a local disinfectant. The frequency of application will depend upon the individual case but in the majority will probably demand the services of the dentist daily for a time at least.

But it is urgently required that dentists work out a method for keeping the disinfectant in longer contact with the tissues. Merely to apply a water solution of arsphenamin, mercurophen or metaphen is almost sure to be followed in a few minutes by high dilution by the saliva, a very brief contact and re-contamination of the tissues probably in a matter of ten minutes.

In the disinfection of pyorrheal pockets it would appear advisable to incorporate 1:500 mercurophen or metaphen into some sort of a jelly or paste capable of being longer retained than a solution. Such are readily prepared and suitably flavored to mask the metallic taste of the disinfectant. In the treatment of spiro-fusillar and spirochetic gingivitis, pastes of arsphenamin prepared with water or glycerin or the powder itself have been applied but I believe solutions are to be preferred and especially one employing 1 per cent. arsphenamin in 50 per cent. glycerin, prepared as follows:

Arsphenamin	0.3 gm.
Hot water or 50 per cent. glucose solution	15.0 c.c.
Dissolve and add Glycerin	15.0 c.c.

This solution gradually becomes dark in color due to the production of oxidation products, but it maintains a high degree of spirocheticidal activity until a deep blackish-green color occurs.

But since it is known that spirochetes may acquire a resistance or fastness to the arsenicals *in vitro*, it would appear inadvisable to use arsphenamin alone over a long period of time; possibly better results may be secured by using it alternately with one of the mercurials mentioned.

But a daily local treatment by the dentist is insufficient. The patient should be carefully instructed in a co-operative treatment to be applied at least three times a day and especially after meals. I believe the dentist should aid in the selection of a tooth brush in order to avoid injury to the gums and teach his patient, when necessary, how to apply it properly. I suggest the use of a tooth paste carrying either mercurophen or metaphen

with or without the addition of arsphenamin as an adjuvant in the treatment of practically all cases. It is true that some commercial dentifrices possess some degree of bactericidal activity, but when these are diluted with water and saliva they are not apt to be sufficiently bactericidal and spirocheticidal to be useful from this standpoint.

I believe that medicated tooth pastes serve a useful purpose in the treatment of all cases and especially those of incipient infection and as a "follow up" after a cure has been effected. The paste should be mildly alkaline in reaction and otherwise acceptable as a dentifrice. A useful prescription is as follows:

Mercurophen or metaphen	0.5 gm.
Tooth paste	100.0 gm.

This gives a 1:200 preparation which appears unnecessarily strong but it is to be remembered that the paste is diluted by saliva and water when used. To this paste may be added 1 gram of arsphenamin but the resulting preparation has a greenish-yellow color not at all compatible with pharmaceutical elegance. So far I have not been able to overcome this objection, although, the addition of 0.1 or 0.2 c.c. of a 1 per cent. solution of basic fuchsin to each 100 grams of the paste improves the color and probably increases slightly its bactericidal activity for gram negative organisms without danger of staining the gums or teeth. The addition of acriflavin also tends to improve the color and aids in increasing bactericidal activity but pastes made up with acriflavin alone in sufficient concentration to be bactericidal when diluted with saliva or water, are apt to be objectionable from the standpoint of staining of the tissues. The same is true of gentian violet and other dyes like brilliant green and crystal violet employed by Bunting and Palmerlee.[85]

Tooth pastes of these kinds can be made agreeable to patients and I believe should be prescribed for all cases during active treatment and as a routine prophylactic against re-infection. They are well borne by the gums and need not be feared from the standpoint of systemic poisoning from swallowing small amounts during application although patients should be informed of their nature and cautioned against swallowing the paste. Both mercurophen and metaphen are slightly less toxic than mercuric chlorid but even were they of the same toxicity, the swallowing of a grain a day would not produce toxic effects and this would correspond to about 10 grams of the paste. It is likely that smaller amounts of mercurophen or metaphen could be used, like 0.1 gm. to 100 grams of paste giving a 1:1000 dilution, but the bactericidal and spirocheticidal effects are less. It is my custom at present to prescribe 0.5 gm. per 100 grams of paste during the active treatment of the disease and to reduce the amount down to 0.1 or 0.2 gm. per 100 grams for routine prophylactic use.

In using these pastes it is well to show the patient how to rub small amounts into the gums by means of the index fingers; the paste is left for at least a minute or two when brushing is done in the usual manner with a brush softened in warm water. As a general rule sufficient saliva is present to give a good lather.

In addition it is sometimes advisable to prescribe a lotion for use several times a day and the following can be recommended:

Mercurophen	0.1 gm.
Peppermint water	100.0 c.c.

These give a 1:1000 solution of mercurophen and bactericidal tests have shown that it is capable *in vitro* of completely sterilizing in one minute an equal part of undiluted saliva in final dilution higher than 1:200,000 or an equal part of a 1:100 dilution of a twenty-four hour broth culture of staphylococci in final dilutions as high or higher than 1:200,000. About a teaspoonful of solution may be diluted with 2 or 3 parts of water, taken into the mouth and left in contact with the gums for several minutes when it should be expectorated and the mouth rinsed with water if the taste is disagreeable. Mercurophen does not form amalgams with metallic fillings of teeth.

Chemotherapy of Cancrum Oris with Arsphenamin and Its Substitutes.—Inasmuch as smears of the secretions of this dreaded infection sometimes show the presence of large numbers of spirochetes and fusiform bacilli, it may be advisable to employ arsphenamin or one of its substitutes in addition to the usual treatment, as suggested by DeSanctis.[86] For this purpose neoarsphenamin may be injected intravenously or sulpharsphenamin intramuscularly in dose of 0.01 gm. per pound of body weight, and it may be advisable to infiltrate the margins of the involved tissues by a series of subcutaneous injections of 1-per cent. solutions of sulpharsphenamin in sterile water in an effort to prevent extension of the infection.

Chemotherapy of Pulmonary Spirochetosis.—While spirochetes are not ordinarily found in the normal bronchial secretions, they may be present in the secretions of some cases of bronchitis, bronchiectasis, pneumonia and lung gangrene, and I wish to discuss the subject, particularly from the standpoint of treatment with arsphenamin and its substitutes, under the general heading of *pulmonary spirochetosis*. Indeed, spirochetes may also invade the pleural cavities with the production of pleural spirochetosis, a case due to *Sp. bronchialis* (Castellani) having been recently reported by Mason.[87] The subject has not received the attention it deserves and it is not at all improbable that cases of acute, subacute and chronic bronchitis are sometimes primarily spirochetic infections, and in bronchiectasis and pulmonary gangrene spirochetes may at least exert an important role as secondary invaders. In some cases of pulmonary consolidations regarded clinically as tuberculous, it is not improbable that spirochetic infection exists and, in gangrene of the lungs following pneumonia, the secondary infection of the involved areas have been known to be spirochetic, with a favorable therapeutic response to the administration of arsphenamin and its substitutes. Doubtless these conditions are frequently overlooked, because the clinical syndromes are not typical and the presence of spirochetes in the secretions overlooked in our search for tubercle bacilli and other bacteria, and because special examinations for spirochetes are not made.

As reported by Rothwell,[88] Greeley,[89] Campbell and Dyas,[90] McNeill[91] and Jackson,[92] the bronchi and lungs may be sometimes infected with the fusiform bacillus and spirochete of Vincent's angina, producing sudden unexplained hemorrhages or lesions that may be clinically and roentgenologically indistinguishable from pulmonary tuberculosis but which heat almost magically under intravenous arsphenamin therapy. Pilot and Davis[93] have recently reported extensive studies in thirty-seven cases of pulmonary abscesses, gangrene and bronchiectasis associated with the fusiform bacilli and spirochetes of Vincent in which pyogens, particularly streptococci, played an important secondary rôle in producing a distinct clinical type of fusospirochete pneumonia. Predisposing lesions about the teeth and gums were usually present suggesting a descending infection; arsenic, particularly neoarsphenamin, exerted a definite therapeutic effect and especially in early cases. In 1907 Castellani[94] described a type of bronchitis due to a spirochete which he believes is a separate species and for which he proposed the name *Sp. bronchialis*. Since then numerous cases have been recorded from different parts of the world, but especially in the tropics, the literature being thoroughly reviewed by Castellani and Chalmers,[95] Fantham,[96] and Bloedorn and Houghton.[97] The disease may manifest itself as an acute attack or it may be chronic or subacute in its nature. In acute cases a chill develops, then fever,

which, according to Castellani, seldom exceeds 39.5° C. This lasts from two to eight days, during which time the patient coughs almost continuously and complains of pains all over the body. The expectoration is scanty, mucopurulent, very seldom containing traces of blood. While arsenicals produce rapid relief, the clinical symptoms may disappear even without treatment. In the subacute type, the general symptoms are similar to those of the acute type, but there may be hemoptysis and bronchitis, with slight crepitations. In the chronic type, the disease may have been slow and insidious in onset, or the patient may give a history of previous acute attacks. When he comes for treatment he has a chronic cough, the sputum is mucopurulent, often blood-streaked, while in many instances there is considerable hemoptysis. There may be moist or dry rôles or consolidation areas. In many cases there is a daily rise of temperature, sometimes reaching as high as 40.5°C.

The disease may be simple or it may be complicated by pneumonia, pulmonary gangrene, empyema, tuberculosis of the lungs, moniliasis, paragonimiasis or rhinitic spirochetosis. While a certain proportion of cases will be found to be free from complications, a large share of them will probably prove to be primarily cases of pulmonary tuberculosis with a complication of bronchospirochetosis. In either instance it is extremely important to examine for these spirochetes the sputum of all persons giving a history of hemoptysis. If the spirochetes are found to be the primary agents of the disease, relief is easily effected by intravenous injections of arsphenamin or neoarsphenamin. If the disease is complicated by some other infection, then spirochetosis can be eliminated, leaving the physician free to treat the primary agent of the disease.

In addition to these three forms of spirochetic bronchitis, Violle[98] has described a type termed *hemorrhagic bronchitis with spirochetes*, in which the secretion of the bronchial mucosa is abundant, nearly a quarter of a liter in twenty-four hours. It is tenacious, stringy, viscous, homogeneous, of a bright rosy color, resembling gooseberry juice. It is sufficient, writes Violle, to have seen it once, to escape the danger of confounding it with tuberculous hemoptysis. The general condition is good, often, indeed, very good; there is no fever; the expectoration contains spirochetes in great abundance. The organisms show an extraordinary polymorphism, and this variation in their shape and dimensions is one of their special characteristics. The prognosis is generally favorable, the bloody expectoration ceasing after ten to fifteen days, with fairly rapid recovery; relapses and chronic bronchitis, however, may follow with periods of exacerbation.

During the World War Nolf and Spehl[99] described eleven cases of another type somewhat different from those described by Castellani and Voille, in which a bronchitis or bronchopneumonia was especially characterized by the fact that the breath and expectoration became fetid rather early in the disease and for which they proposed the name "*fetid spirillar bronchitis*." In addition to the fetid secretions and breath, there was high, remittent fever with no tendency to fall spontaneously, progressive loss of strength, dyspnea on the slightest effort, and more or less cyanosis.

In the United States about twenty-four cases of bronchial spirochetosis have been reported by Kline,[100] Dick,[101] Davis and Pilot[102] and Kline and Blankenhorn.[103] Clinically, some of these were first confused with tuberculosis, abscess, and pneumonia. The sputum in some was jelly-like and blood-tinged, in some hemorrhagic, in some purulent, and in others brown and foul smelling. The disease has occurred somewhat more frequently in males, the patients ranging in age from four to seventy-six years, and recovery has been reported in the majority. Faust[104] has described a series of cases observed in China.

Whether these types of bronchitis and bronchopneumonia are actually caused by a new specific species of spirochetes or by spirochetes from the mouth belonging to the several varieties occurring about the gums and especially described by Noguchi, can not be stated, since our methods for differentiating the spiral organisms are too inadequate for drawing fine distinctions. It is possible that the spirochete and fusiform bacillus of Vincent's angina may produce a bronchitis, as described by Rothwell[105] in 1910; Mellon,[106] Sinclair[107] and others have described cases of whooping-cough, pneumonia and tuberculosis in which spirochetes and fusiform bacilli were found in the sputum. Not infrequently one finds spirochetes in the secretions of chronic bronchitis and bronchiectasis, sometimes associated with fusiform like bacilli, but always in association with enormous numbers of bacteria and especially staphylococci, streptococci and pneumococci, and for this reason the rôle of the spirochetes is usually in doubt and especially if the patient has a spirochetic gingivitis, which suggests this source for the presence of the organisms in the saliva and sputum.

Cases of spirochetal *pulmonary gangrene* and *abscesses* have been recorded by Rona, Kline and Blankenhorn, Fishberg and Kline,[108] Rawson,[109] Spano,[110] and others. It would appear that spirochetes may produce pulmonary consolidations with abscess formation, and especially spirochetes in association with fusiform bacilli from foci about the teeth and gums, a pulmonary type of Vincent's infection; in addition, it is possible that these organisms may gain access to areas of unresolved pneumococcus pneumonia with the production of secondary infection and gangrene.

As previously stated, the presence of spirochetes in the sputum is readily overlooked unless they are kept in mind and especially tested for. The spirochete of Vincent's angina is generally well stained by carbol fuchsin, but may be decolorized in stains for tubercle bacilli and fail to take up the methylene-blue counterstain sufficiently well. It would appear that smears are best stained by the Fontani method, especially by Noguchi's modification of this stain, and that examinations of this kind are called for almost routinely in cases of chronic bronchitis, with or without bronchiectasis, and gangrene. As stated by Nolf, an interesting point is the greater or less abundance of spirochetes in the expectoration. In certain patients they are very abundant. They may be found, so to speak, in every field of the microscope, sometimes several in each field, even in very thinly spread preparations. But it is not always thus; in other instances, the microörganisms are much rarer. One must sometimes examine a large number of fields before finding one. In a general way, one may say that the gravity of the affection is in direct proportion to the number of the spirochetes. In the fatal cases they are as abundant in the bronchial mucus as is the spirochete of Vincent in the detritus which covers the ulceration of the diseased tonsil. It has seemed to him that the more numerous the spirochetes were, the more fetid was the breath and the expectoration, and it was because in his first patient this fetor was very striking and the number of spirochetes great, that he thought immediately of seeking a relation between one and the other, and recognized the possibility of the pathogenic rôle of the spirochetes. On the other hand, when, under the influence of treatment, the disease tends toward recovery, improvement goes hand in hand with the diminution of the spirochetes in the secretion, a diminution which becomes evident even when the general characters of the expectoration, excepting the odor, have as yet shown no change.

The Wassermann reaction has not been reported upon except in a few cases, but insofar as I could determine in this brief review of the literature, the reactions have been uniformly negative.

Practically all of the writers referred to above have reported favorable results from intravenous injections of arsphenamin and neoarsphenamin in the treatment of spirochetic bronchitis. Nolf and Spehl, writing with particular reference to their type of fetid bronchitis, state that treatment must be long to control the disease definitely. If a series of intravenous injections of neoarsphenamin are given in doses of from 0.45 to 0.6 gm., five or six days apart, a change in the clinical picture, rather slow in its development, may usually be made out. The condition, which, up to that time, has grown progressively worse, shows little by little signs of an improvement, which, interestingly, affect first the elements characteristic of the infection. On the one hand, the fetor of the breath and the expectoration becomes less; on the other hand, there is a diminution in number or even a disappearance of the spirochetes under the microscope. During this early period of arsenical treatment, the fever may remain tolerably high, and the local signs in the pulmonary apparatus are little influenced. It may even be that with the continuation of the arsenic treatment, the disappearance of the spirochetes is brought about without amelioration of the general or local condition.

This circumstance is easily explained when one considers that the spirochetes are far from being the only microörganism to be found in the sputum which contains a particularly varied and abundant bacterial flora. These microörganisms probably add their injurious action to that of the spirochete. It would appear that the lesions produced by the spirochetes are severe, and that, invaded by the microörganisms of secondary infection, they present little tendency to heal. This, perhaps, is the most distinctive character of the affection which Nolf and Spehl have described. Even after the patients had been rendered apyretic, and after their previously purulent expectoration had become mucoid and free from spirochetes, they continued to cough, and auscultation revealed signs of an attenuated but persistent bronchitis. The writers have had to have recourse to the combined action of balsamics, exposure to sun, and respiratory gymnastics definitely to overcome these sequelae which always show an extreme obstinacy. In certain cases they have added to intravenous injections of neoarsphenamin, peptone, administered intravenously every two days.

In pulmonary gangrene, Becher,[111] Steff,[112] Reichmann,[113] Molnar,[114] Curshmann[115] and others have reported favorable results from treatment with arsphenamin or neoarsphenamin and it would appear well worth while to include a series of intravenous injections of one of these compounds at intervals of five to seven days. Since neoarsphenamin is less likely to produce toxic reactions, it would appear to be the remedy of choice, although if hemorrhages were occurring, I believe that sulpharsphenamin by intramuscular or epifascial injection would be indicated in order to reduce to a minimum the effects upon capillaries. Becher,[116] Hirsch,[117] Curshman[118] and Albracht[119] have reported favorable results from the administration of arsphenamin in the treatment of some cases of fetid bronchitis and gangrene of the lungs in which no spirochetes were found. Spano states that neoarsphenamin administered twice weekly by intravenous injection has proven especially efficacious in the treatment of fusospirillar lung abscesses, combined if necessary with surgical or pneumothorax treatment.

Chemotherapy of Tropical Ulcer and Other Localized Spirochetic Infections.—Another form of localized spirochetic infection usually associated with fusiform bacilli is *ulcus tropicum*, an infection, usually of the legs, in the form of ulcers which may be occasionally phagedenic, found in all tropical and subtropical regions of Africa, Asia and America but rarely in temperate zones. Smears generally show numerous spirochetes, associated with *B. usiformis*, which some writers believe are *Sp. vincenti* and others think are a separate species, *Sp. schaudinni* (Prowazek). In differential diagnosis, frambesia, syphilis, oriental sore, tuberculosis, blastomycosis, sporotrichosis, acladiosis and mycosis fungoides, must be excluded.

In addition to local treatment, intravenous injections of arsphenamin and neoarsphenamin have been reported by several writers as successful in some cases. Mercury and the iodids are useless.

Spirochetes and fusiform bacilli resembling those found in Vincent's angina may also produce a form of *ulcerative balanitis*, but this infection yields readily to local treatment. A spirochete (*Sp. aboriginalis*) has been found in granuloma inguinale, but it is now regarded as a saphrophyte rather than the primary etiological agent of this disease; arsphenamin and neoarsphenamin have not proved efficacious, whereas intravenous injections of tartar emetic have yielded excellent results (Chapter XXXIII).

Chemotherapy of Weil's Disease (Spirochetosis Icterohemorrhagica) and Yellow Fever.—Weil's disease, infectious jaundice, is now commonly regarded as caused by *Leptospira icterohemorrhagica*, discovered by Inado and Ido[120] in 1915. Studies by Inado and his associates with arsphenamin in the treatment of guinea-pigs experimentally infected with the leptospira have not yielded very encouraging or definite results, although in some animals the blood and liver were apparently sterilized by intravenous injections of single doses of 0.05 to 0.1 gm. per kilogram. (I surmise that these amounts were meant to read 0.005 to 0.01 gm. per kilogram, therefore corresponding to 0.3 to 0.6 gm. for the adult of average weight.) Noguchi[121] also states that experiments conducted by him in 1917 with arsphenamin, neoarsphenamin, atoxyl and arsacetin, yielded negative results; furthermore, Stokes and Ryle[122] and Stokes, Ryle and Tytler[123] report that arsphenamin has been without therapeutic effect in human cases of the disease and for the present, at least, it must be concluded that arsphenamin and its substitutes are without marked effect and of doubtful value in the treatment of this disease.

These negative results with arsphenamin and its substitutes may be regarded as giving support to the opinion that the leptospira group of organ-

isms forms a type of its own and differs from the other pathogenic genera of *Spirochætoidea*. This is supported by the negative results observed in yellow fever, which Noguchi regards as a leptospira infection. As shown by Noguchi, while arsphenamin and neoarsphenamin are highly poisonous in the test-tube for *Leptospira icteroides*, which he believes is the causal organism of yellow fever, yet in guinea-pigs inoculated experimentally and treated by subcutaneous injections of the compounds, it was extremely doubtful that these drugs mitigated the severity of the infection. Arago,[124] however, reviewing the work of DeBeaurepaire and others in South America, believes that neoarsphenamin, in dose of 0.45 to 0.9 gm. by intravenous injection, exerts a curative effect in yellow fever, but at the present time it must be stated that the results are doubtful and that this disease, like Weil's disease, is not favorably influenced by arsphenamin and its substitutes.

While there are no reports available on the use of arsphenamin and neoarsphenamin in the treatment of *dengue* and *pappataci*, it is likely that the results would be of a negative character as in Weil's disease and yellow fever; Strong[125] has reported that arsphenamin is without curative effects in *verruca peruana*, a disease found on the western slopes of the Andes mountains and resembling in some respects a severe type of frambesia.

Chemotherapy of Spirochetic Infections of the Lower Animals.—As stated in Chapter XXIII, marked success has attended the treatment of *fowl spirochetosis* with the organic arsenicals. Even atoxyl and arsacetin have been employed with success, but arsphenamin and neoarsphenamin, in dose of 0.010 to 0.015 gm. per kilogram by intramuscular or intravenous injection, have yielded much better results in experimental infections with *Sp. gallinarum* (*Spiroschaudinnia marchouxi*). In the natural infections of fowl with this spirochete, however, as well as in spirochetosis of ducks and geese (*Sp. anserina* and *Sp. neveuxii*), the results have not been quite as good, because some are quite resistant, although the majority are apparently cured by one to three injections.

Arsphenamin has also been employed with success in diseases of cattle infected with *Sp. theileri* in Africa, of sheep infected with *Sp. ovina* in the Transvaal, of monkeys infected with *Sp. macaci*, etc.

PART V

CHEMOTHERAPY OF PROTOZOAN AND METAZOAN DISEASES OTHER THAN TRYPANOSOMAL AND SPIROCHETAL DISEASES

CHAPTER XXXII

GENERAL AND SPECIFIC TREATMENT OF THE MALARIAL FEVERS

While systematic and extensive researches in the chemotherapy of protozoan and metazoan diseases have not been made except in the trypanosomiases and spirochetoses, yet several specific remedies are known to exist for other protozoan infections, and notably quinin for the malarial fevers and tartar emetic for the several varieties of cutaneous leishmaniasis. In a way, they do not constitute chemotherapeutic remedies in the sense that arsphenamin and its substitutes are so regarded, because they were not synthesized for these diseases but discovered more or less accidentally by the peoples among whom the diseases existed; but still they fall into the class of chemotherapeutic drugs because of their specific effects upon the microparasites concerned.

Since the discovery of the trypanocidal and spirocheticidal properties of trypan-blue and other dyes, atoxyl, arsacetin, arsenophenylglycin and finally of arsphenamin (salvarsan), it is no wonder that these compounds, as well as quinin and tartar emetic, should have been used in the treatment of other protozoan and metazoan diseases in a more or less blind, "hit or miss" fashion, with the result that a large literature has accumulated upon the use of these drugs in a wide variety of protozoan diseases.

Possibilities of Chemotherapy in Protozoan and Metazoan Diseases.—But the success which has already attended chemotherapeutic investigations in trypanosome and spirochete infections indicates that there is much hope for developing specific remedies for other protozoan diseases, indeed, much more than in the bacterial diseases. In other words, it would appear that the higher the organism in the scale of life the more differentiated its protoplasm becomes, with greater possibilities for the discovery or preparation of chemical agents having a specific parasitropism without injuriously affecting the cells of the infected host. Furthermore, it would appear an easier task to interfere with the life cycle and processes of the protozoa by means of chemical agents sufficiently for their destruction than is the case with the much simpler and more primitive bacteria.

Finally, with many of the protozoa and metazoa infecting mucuous membranes without gaining access to the blood or lymphatic circulations, as in the

case of the intestinal helminths, the problem of chemotherapy would appear to be a simpler matter than attempting to reach and destroy parasites in the tissues, since compounds may be evolved with direct parasiticidal effects and sufficiently non-toxic for the host to permit of administration by ingestion without local corrosive effects or general systemic toxicity through absorption

Difficulties of Chemotherapeutic Research in Protozoan and Metazoan Diseases.—On the other hand however, chemotherapeutic research in the protozoan and metazoan diseases is greatly hampered by our inability to cultivate the parasites or reproduce their diseases in the animals usually employed for laboratory studies. I do not doubt but that if we could successfully produce the human types of the malarial fevers in the lower animals that systematic chemotherapeutic investigations would soon improve treatment with quinin and no one can deny that this is urgently required not only to possibly improve the cinchona alkaloids by synthesizing new compounds but likewise because the tremendous demand for quinin is hardly met by the number of trees available for furnishing the bark.

While, however, numerous attempts to transmit the *Plasmodium malariae* to guinea-pigs, rabbits, monkeys, mice and rats have failed, one of the latest efforts in this direction having been recently made by Bass,[1] yet it is possible, and indeed quite probable, that very useful chemotherapeutic investigations could be conducted with the parasites fo the lower animals, like *P. kochi*, *P. inui*, *P. cynomolgi*, *P. pitheci* or *P. brasilianum* infecting different species of monkeys, *P. canis* of dogs, *P. danilewski* of birds, etc.

Cultivation or propogation of the parasites *in vitro* on artificial media is not essential since parasiticidal activities *in vitro* of chemical agents bears only a broad and general relationship to the far more important question of specific parasitropism *in vivo* in non toxic doses, but yet I believe that future developments in chemotherapy will be based more and more upon fundamental studies of specific combining affinities of chemical agents for the protoplasm of parasites and that much valuable information may be gained by studies *in vitro* with mass cultures of them.

But the essential requisite for chemotherapeutic research is the reproduction at will of the disease under study in the less expensive laboratory animals in order to open up a method for studying the toxicity of new agents for the living parasites in living animals. The ease with which this is accomplished with the trypanosomes and many of the spirochetes accounts in large part for the great success of chemotherapy in these infections. I do not believe that it is necessary to reproduce in the experimental animals all of the pathological lesions exhibited in natural infections of human beings, although, as in the case of syphilis, this is very helpful, since marked tissues changes greatly influence chemotherapeutic activities; but the main requirement is to devise or discover ways and means for producing and maintaining infections in the lower animals with methods for ascertaining the effect or lack of effect or our chemical agent upon the parasites. In the field of protozoan diseases but few attempts of this kind have been made except in malaria.

Owing to the world-wide distribution of the malarial fevers and especially their high incidence in tropical and subtropical countries where chronic infections produce extreme degrees of physical, mental and moral degradation of enormous numbers of individuals, the subject of specific therapy has deservedly commanded a great deal of attention. Indeed, it would appear that the discovery by South American Indians of the curative properties of Peruvian bark for malaria constitutes the first discovery in specific therapeutics and, along with mercury for syphilis, was the only known specific until comparatively recent times. But while there is a popular impression

that quinin in most any form and by most any route of administration is a sure cure for malaria, such is far from being the case and there is much room and urgent need for evolving a superior remedy and improved methods of administration, especially in the treatment of acute subtertian or malignant malaria aestivo-autumnal fever caused by *Plasmodium falciparum* (*Laverania malariae*) and the chronic forms of all varieties.

In many respects the chemotherapy of malaria offers problems quite similar to those later discussed in relation to syphilis. In almost the same manner the matter of the stage of malaria, whether acute, chronic or latent; the sexual and asexual phases of the different varieties of plasmodia; the influence of immunological processes and pathological tissue changes, greatly influence the method of treatment, even though our choice of drugs may be principally limited to the salts of quinin rather than present a broader selection, as is possible in syphilis among the organic arsenicals, mercurials and bismuth compounds.

Of course, an enormous literature has accumulated on the subject of malaria in all of its phases including treatment. It is hardly necessary or profitable even to attempt its review in a treatise of this kind and I shall confine myself to a discussion only of the treatment and especially the specific treatment, with such references to the parasites, their life cycles, pathogenesis, immunity and pathological changes as are directly concerned in these subjects.

Varieties of Plasmodium Malariae in Relation to the Chemotherapy of the Malarial Fevers.—It is now generally accepted that the malarial fevers of human beings are caused by three parasites, namely, *Plasmodium vivax*, producing tertian fever, *Plasmodium malariae*, producing quartan fever and *Plasmodium falciparum* or *Laverania malariae*, producing subtertian fever also known as aestivo-autumnal, malignant or tropical malaria. Additional varieties have been described as pathogenic for man, among the more recent being *Plasmodium ovale* by Stephens,[2] which Huck and Bowden[3] state was recently found in a native of Maryland, but it is likely that this parasite may be a variety of *Plasmodium falciparum*. Many more varieties are known to infect the lower animals, but none of these infect man, and conversely those infecting man do not infect the lower animals, although Mesnil claims to have produced a temporary infection of an orang-utan with *Plasmodium vivax*.

Of the three pathogenic species for man, the first two, namely, *P. vivax* of tertian fever and *P. malariae* of quartan fever, are the most benign and most susceptible to destruction by quinin. This is largely because these parasites circulate in the peripheral blood in which the latter also sporulates, while the former sporulates in the spleen; *P. falciparum* (*Laverania malariae*), on the other hand, sporulates in various of the internal organs and affects the corpuscles so profoundly that they are liable to adhere to the walls of the capillaries and produce profound changes and symptoms by embolism and the local effects of toxins, as coma or paralysis when the brain is involved. Because of the fact that this parasite sporulates in the internal organs and largely in the spleen and bone marrow, it is more difficult to reach and destroy by quinin and especially in chronic infections, after the parasites have produced inflammatory tissue changes.

All three varieties may produce acute and chronic fevers and it hardly requires statement that the acute infections are far more amenable to treatment and even complete cure in the sense of sterilization, than the chronic infections; indeed, we are confronted in the latter by all of the difficulties offered by chronic syphilis and the matter of complete cure becomes doubtful of accomplishment.

P. vivax and *P. malariae* do not tend to localize in any particular internal organ except the spleen, but *P. falciparum*, may involve any or all of the internal organs, producing a variety of clinical types of chronic subtertian or aestivo-autumnal fevers which bid fair to outdo in variety the many clinical types of chronic syphilis. No one has yet raised the question of tissue specificity of strains of plasmodia and especially of *P. falciparum*, and it is not known whether a special strain exists for the brain, producing the meningitic or nervous system localizations on the one hand, with types possessing special tendencies for localiza-

tion in the digestive, circulatory, special sense or other organs, on the other. As in syphilis, I believe the matter of localization of these parasites is largely determined by non-specific factors, among which may be mentioned congenital predisposition and acquired trauma. However that may be, the types of aestivo-autumnal or subtertian fever that may be encountered as a result of localization of the parasites in this or that organ or "system" is bewildering and complex to say the least, and in the malarial districts I would modify Osler's dictum to read: "Know malaria and syphilis in all its manifestations and relations and all other things clinical will be added unto you." Unfortunately, it is just in these multitudinous types of subtertian malaria, and especially chronic malaria, that quinin may fail, although something has been apparently gained in the past few years by combination types of therapy employing methylene-blue and quinin or, better still, arsphenamin or its substitutes with quinin, the arsenicals appearing to increase the ameboid movements of the parasites and tending to rout them out of their tissue strongholds, as it were, into the open circulating blood where they may be more effectively reached and destroyed by quinin.

The Life Cycle of Plasmodium Malariae in Relation to the Chemotherapy of the Malarial Fevers.—But of even greater importance in relation to specific therapy is the matter of the life cycles of the different parasites. The asexual forms and schizonts or undifferentiated sexual forms of all varieties are far more susceptible to quinin than the gametocytes or sexual forms. Indeed, the great problem in the chemotherapy of malaria awaiting solution is the discovery of an agent with greater parasitropism for the sexual forms, that is, for the macrogametocytes and microgametocytes of all species.

When the parasites are first deposited in the tissues by anophelines they are in the form of minute, naked, fusiform bodies called sporozoites, which are very susceptible to quinin and for this reason the drug has proved very efficacious for the medicinal prophylaxis of all types of malaria. These minute parasites now enter erythrocytes, when they are called trophozoites, and develop into larger forms called schizonts; the latter now sporulate or divide into segments producing rosettes of merozoites. These now rupture into the blood stream, each merozoite being a new, naked or free parasite which enters fresh corpuscles to begin again this asexual cycle. It is also possible for them to pass the placenta and enter the fetal circulation, cases of congenital malaria being well known and recently reported again by Forbes,[4] Freire[5] and others, although congenital malaria is much rarer than congenital syphilis, is transmitted only by the mother and never, to the best of my knowledge, by the father in the semen.

As may be surmised, quinin is most effective when the naked parasites are present in the blood or just after they have entered corpuscles, the mature intracorpuscular forms being more resistant. In a general way, the chill of malaria corresponds to the sporulation stage, when the parasites rupture with the discharge of merozoites into the blood stream; the fever stage corresponds to the time when these merozoites are entering fresh corpuscles; the crisis of the attack corresponds to the early or trophozoite stage of intracorpuscular development and the intermittent or afebrile stage, to the time when these young papasites are maturing into the adult forms, shizonts or rosettes. Quinin, therefore, should be available in the blood at the close of the chill to "catch" the young, free or naked merozoites; also during the fever stage to "catch" them as soon as possible after entrance into fresh corpuscles and likewise and especially, during the crisis of the attack, before the intracorpuscular parasites have developed into the mature forms or shizonts. All of this is comparatively simple in uncomplicated tertian and quartan fevers which follow a fairly definite cycle, but in subtertian or aestivo-autumnal fever the cycle may be so irregular as to offer many difficulties and the same is true of double or triple tertians or quartans and especially difficult in mixed infections of any two or all three of these different species of plasmodia.

Furthermore, as stated above, the sexual forms are even more difficult to destroy, and unless a malarial case is promptly and completely cured, these forms are apt to develop in a matter of a few weeks or months. Two forms are recognizable in the blood or organ juices (especially the spleen) known

as the female, or *macrogametocyte*, and male, or *microgametocyte*. When blood containing these is sucked up by an anopheline into her stomach, they undergo morphological changes into bodies called macro- and micro-gametes; these conjugate (zygosis) or fuse into forms called *oökinetes* or *vermicules* and these finally sporulate with the production of numerous *sporozoites* which circulate through the mosquito, finally reaching her salivary glands and proboscis from which they may be deposited into the blood of a human being to begin all over again the asexual and finally, this sexual cycle.

Pathogenesis of Malaria in Relation to Chemotherapy.—Under this heading I refer to the different pathogenic agencies concerned in the production of the malarial paroxysms and the relation of these to chemotherapy.

In the first place, the mere presence of the parasites in the blood may not produce paroxysms of chills, fever and sweat, unless the infection is numerically heavy enough; thus Ross has calculated that in severe malaria about 12 per cent. or approximately 3,000,000,000,000 corpuscles are involved, while if the number of parasites is reduced below 1 for each 100,000 corpuscles—i.e., 250,000,000—they will cause but little disease beyond a gradual enlargement of the spleen and perhaps some anemia and melanosis. Certainly large numbers of parasites can be present in the body and especially in the spleen, without producing much damage, constituting a state designated as latent malaria. As will be shortly discussed, this condition may be due to antibodies or immunological tissue resistance or produced and maintained by the chronic intermittent ingestion of quinin, being quite similar in this respect to the latency of syphilis and equally subject to conversion into active malaria by a reduction in general vitality, trauma or the administration of antimalarial drugs, the latter constituting, as it were, malarial Herxheimer-like reactions.

But very little is known, however, of the poisons or toxins produced by malarial parasites. It is commonly stated that the chills and fever are due to the liberation of a pyrogenetic toxin at the time the parasites sporulate and discharge into the blood; this toxin is also apparently capable of producing some hemolysis or this effect may be due to a second hemolytic poison or malarial hemolysin (hemotoxin) analogous to the hemolysins produced by other protozoa, which I will discuss with more detail later in relation to the nature of malarial hemoglobinuria and blackwater fever. At any rate it would appear that these toxins are excreted by the parasites into the corpuscular hosts followed by liberation into the blood upon the rupture of the infected corpuscles. The pyrogenetic poison is then apparently capable of acting upon non-striped muscle, causing a constriction of capillaries and especially of the skin (goose-flesh of the chill), with stimulation or depression of the cardiac, respiratory and heat regulating centers. This poison, in my opinion, may also alter the corpuscular proteins and especially the hemoglobin to such an extent that the corpuscular fragments act as non-specific protein agents producing in part the chill, fever and sweat, characteristic of non-specific protein or colloidal reactions, so well known nowadays following intravenous injections of vaccines, tissue extracts and certain heavy metals in colloidal suspension. The production of hemolysis by this poison or the second hemolytic toxin, may in turn likewise produce reactions of this kind analogous to the effects following intravenous injections of water, arsphenamin, or other hemolytic agents; and finally, the fragments of corpuscles themselves may produce colloidal shock reactions of chills, fever and sweat exactly analogous to the malarial paroxysm.

In addition to these secreted or exogenous toxins, it is possible that the merozoites and schizonts contain these poisons within their protoplasm as endotoxins and that these may be liberated by the destruction of the parasites by quinin and thereby account for the febrile reactions sometimes observed following quinin administration. In other words, I believe that the malarial paroxysm may be the summation of the effects of the following: (*a*) the liberation of preformed toxins stored in the corpuscles and liberated by sporulation; (*b*) the liberation of endocellular toxins of the same kind following quinin or other disintegration of the parasites; (*c*) the effects of non-specific protein reactions from the transformed corpuscular proteins and (*d*), the effects of colloidal shock reactions due to the corpuscular fragments.

Quinin, however, is not a neutralizer of these toxins or protein-colloidal agents, and just as part of the febrile reaction in syphilis, following the administration of arsphenamin and its substitutes, may be due to the liberation of *Sp. pallida* toxins, so quinin may liberate plasmodial toxins; quinin, however, may, and very probably does, tend to correct or prevent the effects of these plasmodial toxins and colloidal agents upon the cardiac

muscle, respiratory and heat regulating centers as it may in the case of pneumococcus and other bacterial toxins; but the actual neutralization of the plasmodial toxin or toxins, as well as of the protein poisons, requires the operation of the patient's immunological mechanism.

In addition to these acute effects, we may have in chronic malaria the tissue changes produced in the spleen, bone marrow and other organs characterized especially by chronic hyperemia and fibrosis due to the action of these toxins as well as to the inflammatory effects of the malarial pigment and protein poisons. These chronic tissue changes are due entirely to the plasmodia and not to quinin since I have found in my experiments that even the prolonged administration of quinin to rabbits in dose corresponding to one half grain or 0.03 gm. per kilogram of the bisulphate by ingestion daily for three to six months, did not appear to produce any of the tissue changes characteristic of malaria, although intramuscular and especially intravenous injections of large repeated doses were observed to produce profound tissue changes.

Pathology of the Malarial Fevers in Relation to Chemotherapy.—There is nothing in the acute malarial fevers, from the standpoint of pathological tissue changes, that materially influences the question of chemotherapy. Even in chronic malaria the characteristic vascular changes and interstitial fibrosis do not militate against the access of quinin and other plasmodial poisons to nearly the extent that *Sp. pallida* is protected by vascular sclerosis and organized syphilitic exudates. The chief difficulty in the treatment of chronic malaria, and especially of the subtertian or aestivo-autumnal type, is not that drugs fail to reach the parasites, but that it fails to penetrate or destroy them and especially the sexual forms. Indeed, in malaria, the parasites are generally accessible in the capillaries, in sharp contrast to the perivascular and deeper tissue localizations of spirochetes and trypanosomes. When confronted with a patient presenting an enlarged fibrotic spleen or similar involvement of the organs of the nervous, respiratory, digestive, urogenital systems, etc., our first and natural inclination is to ascribe the failure of quinin therapy to the enmeshment of the plasmodia in fibrous tissue and exudates out of reach of the drug. I do not deny that this may occur in part; indeed, histological examination of such organs shows that it does occur, but not to the same extent as in chronic syphilis. In syphilis of the central nervous system and especially in paresis, as well as in cardiovascular and other types of visceral syphilis, it is largely a matter of evolving a spirocheticidal drug capable of escaping from sclerosed vessels and soaking into the parenchyma to reach the spirochetes; in chronic malaria it is rather a matter of evolving a drug capable of destroying the sexual forms of the plasmodia after being brought in contact with them.

Immunity of Malaria in Relation to Chemotherapy.—Many of the immunological aspects of the malarial fevers are of great interest and practical importance. Does natural immunity to the parasites of *Plasmodium malariae* exist among human beings? Does antibody-production or any other immunological change occur in malaria to a therapeutic threshold? Is immunity to malaria transmissible from mother to off-spring? Does one type of malaria afford protection against other types? Do immunological processes ever bring about complete and spontaneous recovery from these infections? Is the latency of malaria an immunological phenomenon? Are there any drugs capable of stimulating or increasing immunological resistance to the plasmodia? Does re-infection and super-infection occur in malaria? These and other equally important questions are concerned

in the immunity of the malarial fevers which may be briefly discussed since they concern the subject of chemotherapy in these diseases.

It is highly probably that natural immunity to *P. vivax, P. malariae* and *P. falciparum* (*Laverania malariae*) is quite rare among human beings. Even in the malarial districts women who have developed a high degree of acquired immunity do not apparently transmit this state to their off-spring and infections among the young are very frequent. Of course, in these districts instances of apparent immunity among adults are not lacking, but these are to be ascribed to acquired immunity as the result of infection rather than to natural resistance. Furthermore, it is to be expected that fortuitous circumstances may account for escape from infection when bitten by infected anophelines. Human beings, however, enjoy an absolute immunity to the malarial plasmodia of the lower animals and *vice versa;* why this is so cannot be stated. There is nothing to indicate that the mechanism is due to antibodies in the blood of human beings for these parasites; rather, in my opinion, it is due to the fact that the human tissues fail to supply a pabulum requirement.

Do human beings ever recover spontaneously from malaria unaided by quinin? It would appear to be well established that some infections may wear themselves out and especially the quartan fevers. This result is apparently due to the production of immunological principles inimical to the parasites, but in the majority of cases, the infection passes into a state of latency rather than complete extinction, which, as in syphilis, may amount to what may be termed "clinical cure" without complete sterilization. At any rate, individuals who elect to "fight off" malaria unaided by quinin have but a poor chance for success in the sense of complete recovery. However, spontaneous recovery may apparently occur in cases of chronic syphilis inoculated with tertian malaria as a form of treatment; but this artificial or inoculation malaria has other features differing from natural infections although the occurrence of spontaneous recoveries indicates that the human may develop a definite immunological resistance to malaria.

Very little is known of antibody-production in malaria. Apparently antitoxins are produced for the pyrogenetic and hemolytic poisons and these are also capable of destroying some of the parasites as indicated by the results of Casagrandi's experiments with pigeons infected with *Hemoproteus* (*Halteridium*). In light and exceptional cases, especially in infections with *P. malariae* of quartan fever, all of the parasites may be destroyed, but the patient may be re-infected subsequently by plasmodia of the same or other species. In other words, the immunity of malaria rarely reaches a state of high perfection, not even as high as is developed in syphilis. At most, the acquired immunity is sufficient for throwing the disease into a state of latency with exceptional cases of complete recovery; but the latency is rather easily broken down by chills, starvation, the onset of another acute disease and the presence of some other chronic ailment, which may often be but slight, so that exacerbations are of frequent occurrence. In the great majority of cases, however, the immunological reaction is sufficient for neutralizing the hemotoxic effects of the malarial poisons, and especially those produced by *P. vivax* of tertian fever, but slightly less so for those produced by *P. malariae* of quartan fever and much less for those elaborated by *P. falciparum* or *Laverania malariae* of malignant or aestivo-autumnal fever. I will, however, discuss this subject shortly with more detail in a consideration of the mechanism of the malarial and quinin hemoglobinurias and the nature of blackwater fever.

Furthermore, even if cure is effected by natural or medicinal means, the immunity is of very short duration, since re-infection may readily occur by plasmodia of the same or other species. Even while an individual is suffering with one type of infection, he may become super-infected with another species of parasite, producing mixed infections. However, the adult natives of malarial districts are certainly more resistant to re-infection and super-infection than immigrants, indicating that the antibodies are somewhat effective; but just as the resistance of syphilis is dependent upon the presence in the tissues of living spirochetes, so it would appear that the resistance of malaria is in reality due to clinically latent infection rather than to congenital transmission of resistance or the retention of antibodies after the complete eradication of the plasmodia from the blood and fixed tissues.

There is little or no hope, therefore, for developing a means for active or passive immunization against malaria, even though we should be eventually successful in cultivating the parasites at will and in mass. Just as in syphilis, the human body cells do not appear capable of producing large amounts of antibody to the parasites in a living state and undoubtedly much less to dead parasites in the form of a vaccine. It is very doubtful if a successful serum therapy can be developed, although the horse or other lower animal may react better than human beings. But at any rate, nothing worth while has been developed so far in malaria in the way of vaccine or serum therapy and our present knowledge of the immunology of the disease gives but little encouragement to investigations in this field.

It is apparent, therefore, that medicinal treatment is the main hope of prophylaxis and recovery in the malarial fevers. But may quinin stimulate antibody-production? May it act upon the antibody-producing tissues in such a way as to increase their response to antigenic stimulation by the proteins of the plasmodia, as some believe that mercury and the organic arsenicals increase antibody-production in syphilis? May the beneficial effects of methylene-blue and arsphenamin in malaria be ascribed to this kind of mechanism? I shall shortly discuss the antiplasmodial mechanism of these drugs in more detail, but here it may be stated that there are no grounds at all for assuming that quinin, methylene-blue and the arsenicals materially aid in the curing of malaria by increasing antibody-production.

Quinin and Other Cinchona Alkaloids in the Chemotherapy of the Malarial Fevers.—The best known and most effective destroyers of all varieties of the malarial plasmodia are the natural alkaloids of Peruvian bark (*Cinchona officinalis*) and their synthetic salts. The curative properties of the bark itself were doubtless known to the natives of Peru before being brought to the attention of the early Spanish explorers of this country about 1600 A.D. In 1683, the Countess of Chinchon, then residing in Peru, was cured of an attack of terian fever by the powdered bark of these trees, called by the natives "quina-quina;" four years later she introduced it into Europe for the treatment of malaria on her estates near Madrid and the tree was subsequently named by Linnaeus in her honor, but who, by the way, misspelled her name. In 1820 Pelletier and Caventou prepared the alkaloid quinin and since then a large number of other alkaloids have been isolated from the bark and additional ones, like hydroquinin and optochin, synthesized from quinin.

Naturally, a good deal of attention has been given to the question of the comparative toxicity and antimalarial properties of these different alkaloids, but the consensus of opinion appears to be that the natural alkaloids are superior to the newer synthesized compounds. Indeed, the number of quinin compounds before the profession is most bewildering and especially in view of the fact that almost all of them have been cham-

pioned by some one as possessing superior properties. One of the latest comparative studies has been made by MacGilchrist,[6] with the general result that of the five natural alkaloids, quinin, quinidin, cinchonin, cinchonidin and quinoidin and the two quinin derivatives, hydroquinin and ethylhydrocuprein (optochin), the relative therapeutic values were determined in the following order, hydroquinin being the most and quinoidin the least effective: (1) hydroquinin hydrochlorid, (2) cinchonin sulphate, (3) quinin sulphate, (4) quinidin sulphate, (5) optochin hydrochlorid, (6) cinchonidin sulphate and (7) quinoidin. For all practical purposes, the first four were found to be of equal value, but if any difference does exist, cinchonin is to be regarded as superior to quinin and quinidin as inferior. As regards unpleasant by-effects of these alkaloids, buzzing in the ears was most frequently associated with quinin and quinidin; amblyopia, with quinin and cinchonin; diarrhea, with cinchonin if administered for over a week; nausea, with quinoidin. Cinchonidin, even in large doses, caused no unpleasantness of any kind.

It is not surprising that a host of other vegetable compounds should have been advocated from time to time to substitute for quinin in the treatment of malaria or to act as adjuvants; the sheet anchors of treatment are quinin, cinchonin and their salts. Ethylhydrocuprein (*optochin*), and particularly its soluble hydrochlorid, being found more bactericidal for the pneumococcus than quinin and other natural alkaloids, has been advocated by Izar[7] and others for the treatment of malaria, but is now known to be actually less effective than quinin and more toxic; the same is true of isoamylhydrocuprein (*eukupin*) and isoocytylhydrocuprein (*vuzin*).

Absorption and Elimination of the Cinchona Alkaloids in Relation to the Chemotherapy of the Malarial Fevers.—It is commonly believed that quinin bisulphate and other salts of quinin and cinchonin are largely absorbed from the stomach, since quinin may appear in the urine as early as fifteen minutes after ingestion. MacGilchrist claims that absorption is largely from the small intestine, but it would appear that the acidity of the stomach facilitates absorption to a greater degree than the alkalinity of the small intestines. At any rate, absorption after ingestion is ordinarily quite rapid and usually sufficient for the treatment of the majority of cases of malaria.

When quinin and cinchonin reach the stomach, it is probable that minute portions are converted by the hydrochloric and organic acids into quinicin (quinotoxin) and cinchonicin (cinchonotoxin), but these substances are not nearly as toxic as first surmised and the myth of incompatibility of quinin with acids under these conditions has been long since exploded. Indeed, one of the drawbacks to the oral administration of quinin and especially in the treatment of chronic malaria, is the frequent occurrence of anacidity or hypo-acidity of the gastric juice which hinders absorption of the drug and requires the administration of a mineral acid like hydrochloric or sulphuric acids. Furthermore, regurgitation of the alkaline duodenal contents and especially in "bilious remittent fever," tends to neutralize the stomach acidity and greatly interferes with the absorption of quinin. Failure of quinin administered by ingestion to control malaria is frequently due to hypo-acidity or regurgitation of bile and it is sometimes necessary to first cleanse the stomach preliminary to the administration of the drug and to accompany its administration with a diluted acid.

The salts of quinin and cinchonin are also administered by intramuscular and intravenous injection and especially in cases of severe malaria of all types associated with vomiting or coma interfering with administration and absorption by the oral route. These methods have been particularly serviceable in the treatment of aestivo-autumnal or malignant malaria and S. Solis-Cohen[8] has especially advocated deep intramuscular injections of the double salt known as quinin and urea hydrochlorid in dose of one gram (15 grains) dissolved in a syringeful of sterile hot water. As will be shortly discussed, however, quinin produces a considerable degree of local irritation and intravenous injections must be given with great care on account of the production of dangerous reactions. It is certain that intramuscular injections are to be preferred to intravenous injections when the oral route cannot be employed, but it is possible to give intravenous injections with considerable safety if the drug is highly diluted and slowly injected, and this route is sometimes required for the prompt checking of severe malarial infections and especially aestivo-autumnal, subtertian, tropical or malignant malaria.

After the absorption of quinin, about 60 to 90 per cent. is destroyed in the body and the balance is eliminated in the urine; none or but traces have been found in the feces and other excreta. Independently of the dose or route of administration the elimination of quinin in the urine ordinarily begins in fifteen to thirty minutes, reaches the maximum in

four to ten hours, and is practically completed in twenty-four hours, although traces may be found for several days. In hypo-acid or anacid states and in bilious vomiting, however, absorption is delayed or does not occur and for this reason, when quinin is administered by stomach, it is sometimes useful and practical to apply a test for quinin in the urine as a means for determining whether or not absorption is occurring. In severe nephritis and cardiac decompensation elimination may be delayed. Sometimes it is found that patients do not take the quinin ordered and the following urinary test is advocated by Castellani and Chambers as a means for determining whether or not absorption is taking place: (*a*) Place 2 c.c. of *filtered* and *clear* urine in a clean test-tube. (*b*) Add 0.5 c.c. of *Tanret's reagent* (3 gm. potassium iodid, 1 gm. bichlorid mercury, 20 c.c. of glacial acetic acid and distilled water to make 60 c.c.). In the presence of quinin or albumin, an *opalescence* or *white cloud* appears. (*c*) Add a few drops of absolute alcohol, when the precipitate, if due to quinin will disappear, while that caused by albumin will remain. The reaction appears in about two hours after taking a dose of quinin and persists for twenty-four hours after a dose of 5 grains, and for forty-eight hours after a dose of 20 grains of the drug.

When quinin is administered by ingestion, the concentration in the blood remains quite constant for about twenty-four hours, as shown by Hartman and Zila;[9] after intravenous injection, the concentration sinks rapidly at first and then more slowly. In the blood it would appear, according to Baldoni,[10] that most is contained in the erythrocytes, but the brain, liver and spleen have been found by Baur and his colleagues[11] to contain more than the blood. After intramuscular and intravenous injection, traces may be found in the bile and saliva, but most is eliminated in the urine. This tendency for the rapid destruction and elimination of quinin adds to the difficulties in treatment and especially of chronic malaria when the presence of the drug is required over a long period of time; on the other hand, however, it greatly reduces the chances of producing toxic tissue reactions and especially of the liver and kidneys, which may occur after the prolonged administration of mercury, arsphenamin, etc.

Toxicology of the Cinchona Alkaloids in Relation to the Chemotherapy of the Malarial Fevers; Allergic Hypersensitiveness to Quinin.—The untoward or toxic effects of quinin, cinchonin, and other alkaloids of Peruvian bark are so well known under the term "cinchonism," that they scarcely required description in this treatise. The early symptoms are headache, tinnitus, and blurred vision doubtless due to vascular disturbances in the vessels of the meninges, eye and ear, while in severe or prolonged poisoning, the vasculoconstriction producing ischemia of the retina and ear may be followed by atropic changes in the cells of the retina, optic nerve and spiral ganglion, resulting in blindness and deafness, at first partial, later complete. Very large doses may produce difficulty of speech, confusion of ideas, delirium, coma and respiratory failure due to paralysis of the center, the latter being the usual cause of death. Susceptibility to quinin and cinchonin varies among different human beings; as a general rule, individuals with malaria and pneumonia can stand much larger doses without signs or symptoms of cinchonism than normal, healthy persons. This is analogous to the increased tolerance of syphilitics for mercury and the iodids. On the other hand, individuals may be hypersusceptible to quinin, although true allergic hypersensitiveness is so uncommon that the subject hardly requires the amount of discussion devoted to it. However, it is well for individuals about to pass into malarial districts to determine their sensitiveness to quinin by taking one or two grains to determine tolerance in case it is advisable to take quinin for prophylactic purposes or if the drug would be required should they unfortunately contract the disease.

In hypersensitive individuals the swallowing of even traces of quinin may produce the most marked effects of cinchonism including a variety of scarlatinal, urticarial, purpuric and other rashes. My colleague, Dr. Boerner, who is hypersusceptible to quinin, has

described a skin test[12] for the condition consisting of the application to abrasions of the skin of a drop of 1:10 to 1:1000 solutions of the bisulphate, a marked urticarial reaction occurring in a few minutes. O'Malley and Richey[13] have also described a similar skin reaction to quinin and, curiously, reactions did not occur with cinchonin or cinchonidin nor were the individuals clinically susceptible to these closely allied compounds, suggesting that, in cases of quinin hypersensitiveness, it may be possible to administer one of the salts of cinchonin.

These instances of allergic hypersensitiveness are invariably congenital or natural allergies; I do not know of any of acquired sensitization. Intolerance for quinin, however, may be acquired as a result of prolonged administration, but this is much less likely to occur than intolerance for mercury and the organic arsenicals, since so little quinin is stored up in the body. In some cases of this kind it is possible to administer cinchonin without ill effects, but if not, and if quinin is required for the treatment of a malarial infection, it is worth while to attempt densensitization by the methods employed by Heran and Saint Girons and O'Malley and Richey.

It is stated that the fatal dose of quinin is about 8 grams for an adult (approximately 130 grains), but a dose of 30 grams of the sulphat has been recovered from, probably because this salt is but feebly soluble and much may not have been absorbed. Cohen, Heist and I[14] have found that the maximal tolerated (10 days) doses of several quinin preparations for rabbits and mice were approximately 0.02 to 0.06 gm. by intravenous and 0.03 to 0.08 gm. per kilo by intramuscular injection. Toxicity by intravenous injection is greatly influenced by the degree of concentration of the solutions and rate of injection, but if the average maximum tolerated dose of the dihydrochlorid is taken as approximately 0.05 gm. per kilogram in 5 c.c. of sterile water (1:100), it is found that this is equivalent to 3.5 grams for a 70 kilogram adult, so that the intravenous injection of 1 gram (15 grains) is well within the limits of safety for most individuals. It is frequently advised to give this amount in 10 c.c. of water by syringe injection (1:10), but I believe it is much better to give it in 100 c.c. of sterile normal saline solution by gravity injection in order to minimize the chances of producing toxic reactions. Furthermore, in the type of case requiring intravenous injections, the saline infusion alone is of therapeutic value.

All of the salts of quinin and cinchonin injected intramuscularly and subcutaneously produce varying degrees of local irritation; in the rabbit, I have observed necrosis of muscle cells, polymorphonuclear leucocytic infiltrations, hyperemia and hemorrhages. Some salts like quinin and urea hydrochlorid and quinin with urethan are much less painful than the bisulphat, but in a general way the degree of local irritation varies according to the percentage of quinin or cinchonin in the molecule. Deep intramuscular injections are much less painful than subcutaneous injections; indeed, the latter should not be employed at all and in giving the former, due care should be exercised against depositing any of the drug near large nerves or in the subcutaneous tissues. According to my limited experience, epifacial injections described in Chapter LX are better borne than intramuscular injections and are to be preferred for ambulatory patients.

Since quinin and cinchonin do not tend to accumulate in the tissues, prolonged administration is not usually followed by any evidences of nephritis, hepatitis or other tissue reactions, although gastro-intestinal changes may occur. Cornwall[15] states that intramuscular and intravenous injections of quinin to rabbits over long periods of time may produce some damage of the epithelium of the kidneys and suprarenal glands, with increased disintegration of erythrocytes in the spleen. I have observed that intramuscular and intravenous injections of rabbits with quinin dihydrochlorid, in dose of 2 grams per 60 kilograms of weight every 5 days for twelve to thirty-six injections, sometimes produced nephritis and marked vascular changes; also passive hyperemia and cloudy swelling of the liver and hemosiderosis of the spleen, but these changes were usually slight and not apparent at all in some animals. Larger doses, however, produced more intense changes of the same general character along with hyperemia and perivascular round cell infiltrations of the meninges. I have the impression, however, that rabbits are less susceptible to the vascular changes of cinchonism than human beings; at least this appears to be true of the retinal vessels insofar as one may determine by opthalmoscopic examinations of the eye-grounds, as already discussed in Chapter VI in refernce to the toxicity of ethyl-hydrocuprein hydrochlorid.

Of additional interest in connection with the toxicity of quinin and especially in relation to intravenous injections, are its hemolytic properties, but this subject may be now discussed in relation to quinin and malarial hemoglobinurias and the etiology of blackwater fever.

Malarial and Quinin Hemoglobinurias and the Nature of Blackwater Fever in Relation to Chemotherapy.—It is well known that in exceptional cases of chronic malaria, the administration of quinin, even in single small

doses by ingestion, may produce an acute fever characterized by hemoglobinemia and hemoglobinuria. This condition has been generally designated as "quinin hemoglobinuria," but I am confident that it is a misnomer and that the condition is not to be ascribed to quinin itself but rather to the infection.

Hemoglobinemia, and especially hemoglobinuria, sometimes occurs in malarial infections due to *P. falciparum* (aestivo-autumnal) and exceptionally in fever due to *P. malariae* (quartan) independently of quinin; this condition is designated as "malarial hemoglobinuria," and is usually relieved by the administration of quinin.

Hemoglobinemia and hemoglobinuria, associated with great blood destruction, jaundice, fever, chills, headache, vomiting, delirum, etc., sometimes develops in the malarial districts and is known as "blackwater fever," "bilious hemoglobinuric fever," "bilious remittent fever," "malignant bilious fever," etc. The etiology is obscure; some believe it is due to malaria; others and especially Stephens, believe it is due to the effects of chronic malaria and quinin, and others still, like Castelleni and Chambers, that it is due to some unknown agent which may be a parasite transmitted by the bites of an unknown arthropod. Undoubtedly the majority of cases show plasmodia in the blood and these are benefited by quinin; in most instances *P. falciparum* has been found, but *P. vivax* or *P. malariae* may be present. Stevens and also Thomson[15a] believe that the disease is undoubtedly due to repeated intense infection with *Plasmodium falciparum*—usually over a prolonged period of several months or years and that it should not only be controlled, but absolutely abolished, by anti-malaria measures.

All three conditions, therefore, are characterized by increased blood destruction; in one, this is ascribed to quinin; in another, to plasmodia and in the third, to malaria and quinin or to an unknown agent.

In the first place, is quinin hemolytic? If so, are the erythrocytes of chronic malarial cases more susceptible to the hemolytic action of quinin than the corpuscles of normal healthy subjects? In 1909, Barratt and Yorke demonstrated that quinin in alkaloidal form and as the dihydrochlorid were hemolytic *in vitro*, but expressed the opinion that it was not possible to place enough in the blood stream to produce hemolysis, because of the toxicity of the drug. Others have stated that while quinin was not directly hemolytic *in vivo* that it may be indirectly hemolytic by other ways, as, for example, by lowering the osmotic tension of the plasma or in some way modifying the response to other hemolytic agents. Stephens and Christopher found that 0.001 to 0.00082 gm. of quinin hemolyzed 1 c.c. of a suspension of normal human cells at 37°C. and Castellani and Chambers believe that quinin hemoglobinuria is due to hemolysis of erythrocytes *in vivo* by the drug. I cannot agree, however, with this statement and in my opinion the primary etiological factor in so-called quinin hemoglobinuria is really a malarial infection.

In my experiments various salts of quinin were found to be slightly hemolytic for washed human corpuscles *in vitro*, but this hemolytic effect was greatly inhibited by plasma, just as the hemolytic effects of arsphenamin *in vitro* are inhibited by plasma and serum. For example, in tests employing 1 c.c. of varying dilutions of drugs in saline with 1 c.c. of 1-per cent. suspensions of washed cells or 0.2 c.c. of whole blood, the highest dilutions showing hemolysis after an incubation of one hour at 38°C. were as follows: 1:300 to 1:1800 with washed blood cells and only 1:100 to 1:300 with unwashed cells.

The corpuscles of one chronic case of malaria (*P. falciparum*) yielded identical results. The intravenous injection of rabbits with doses of the bisulphate and dihydrochlorid as high as 0.020 gm. per kilogram, corresponding to 1.5 gm. for the human adult of average weight, has never produced hemoglobinemia or hemoglobinuria, although among some rabbits treated with repeated intravenous and intramuscular injections of these compounds in dose of 0.01 gm. per kilogram, the urine has shown the presence of erythrocytes and albumin, and the kidneys the presence of acute nephritis in which the glomerular tufts were hemorrhagic with collections of erythrocytes in the tubules. In other words, while salts of quinin are feebly hemolytic in whole blood, it is not possible to introduce enough into the circulation of living rabbits to produce hemoglobinemia or hemoglobinuria, unless a toxic nephritis is produced with the passage of blood into the urine, as in other types of kidney injury. I believe the same conditions pertain to human beings and that it may be

stated that quinin itself in the doses ordinarily administered does not produce hemoglobinemia or hemoglobinuria.

On the other hand, the malarial plasmodia and especially *P. falciparum*, may produce some profound change increasing blood destruction. This does not appear to be in the nature of an increased fragility of the erythrocytes; at least they are not of increased susceptibility to the hemolytic activity of quinin. Rather, I believe the condition is due to some alteration of the spleen and bone marrow caused by the plasmodia and especially some change in the spleen whereby the physiological activity of this organ in blood destruction is greatly augmented to reach pathological proportions. At the same time, some profound change has occurred in the blood either in the way of a decrease of antibody counteracting the activity of the plasmodial hemotoxin or some chemical change of unknown character associated with the presence of free hemoglobin or bile and counteracted by calcium, since the administration of calcium lactate by mouth or calcium chlorid intravenously are known to afford relief. Quinin hemoglobinuria, therefore, is a misnomer and whenever the administration of this drug is followed by the presence of hemoglobin or corpuscles in the urine, I believe it is because the drug has stimulated foci of latent plasmodial infection in a manner analagous to the Herxheimer reaction of syphilis. In my opinion, therefore, quinin hemoglobinuria, malarial hemoglobinuria and blackwater fever are all due to the one essential primary etiological agent, namely, the malarial plasmodia. These parasites are responsible for the change in the spleen and other organs concerned in blood destruction producing an exaggeration of this process and resulting in the production of secondary changes in the blood, especially the presence of unchanged hemoglobin and bile, responsible for an alteration in the coagulation and bleeding time with an increased tendency for hemorrhage. Since the most severe chronic infections are due to *P. falciparum*, it is to be expected that these conditions will occur most frequently in aestivo-autumnal fever, but that they may also occur in chronic tertian and quartan fevers. While quinin may be expected to be most capable of stimulating latent chronic malarial infections, I would not be surprised to learn that other agents may produce the same thing and especially intravenous injections of arsphenamin and neoarsphenamin.

Why these changes occur in some cases and not in others cannot be stated; nor why blackwater fever and its milder form, malarial hemoglobinuria, affect only some cases or are especially prevalent in certain districts. In my opinion, these malarial hemoglobinurias are essentially similar to paroxysmal hemoglobinurias, which we now know are frequently due to *Sp. pallida*, but doubtless may be caused by chronic bacterial infections in which the essential change is due to some disturbance of the organs concerned in blood destruction with secondary chemical changes in the blood.

In relation to treatment, I believe that the administration of quinin is indicated in all cases, although in quinin hemoglobinuria, which, as stated above, I believe is really a malarial Herxheimer reaction, and in blackwater fever, which, I believe, is an acute severe type of malarial hemoglobinuria or Herxheimer reaction in case the attack is initiated by the administration of quinin, it may be necessary to administer calcium to check the hemorrhagic diathesis while the infection is being attacked by quinin. But this subject will be shortly discussed with more detail.

Mechanism of the Plasmodicidal Activity of Quinin in the Treatment of the Malarial Fevers.—How do quinin and cinchonin destroy the malarial plasmodia? This is a subject of fundamental importance and interest not

only in relation to the treatment of the malarial fevers, but also in relation to the science of chemotherapy in general.

Does quinin cure malaria by a direct toxic action on the protoplasm of the parasites? Unquestionably quinin is a poison for the malarial protozoa, just as it is toxic for the protoplasm of other cells possessing ameboid movement, as the various infusoria, leukocytes, spermatozoa, etc. It is stated that *in vitro* 1: 10,000 solutions are capable of immediately arresting the movements of the parasites followed by such morphological changes as indicate their death. Bass and Johns have shown that quinin inhibits and destroys the plasmodia in cultures and it has been calculated that a 1: 20,000 dilution in the circulating blood is sufficient for the destruction of trophozoites and other asexual forms of the parasites. At least a dose of 0.2 gm. (3 grams) per 70 kilograms (145 pounds) is capable of ridding the blood temporarily of the early asexual forms of plasmodia and if this dose were absorbed into 4000 c.c. of blood the dilution would be 1: 20,000. In practice, however, several doses of this would follow at intervals of three or four hours so that the concentration would be higher in most instances, but it is well known that 2 to 5 grains of quinin per day is sufficient for prophylactic purposes, that is, capable of destroying the sporozoites deposited in the skin by the bites of infected anophelines. I believe, therefore, that we may logically conclude that quinin may cure malaria by a direct parasitropic effect upon the plasmodia.

But may quinin first undergo some change or unite with some constituent of the blood to form a more toxic substance which is the actual plasmodocidal agent, just as arsphenamin is believed to be first converted into an oxid of enhanced spirocheticidal and trypanocidal properties? To the best of my knowledge there is no evidence to indicate the operation of a mechanism of this kind.

May quinin destroy the plasmodia, by stimulating the production of antiplasmodial substances by the body cells in the nature of antibodies in a manner analogous to the production of antispirocheticidal substances by arsphenamin and its substitutes, which some believe is the mechanism involved in syphilis? To the best of my knowledge there are no data to indicate a mechanism of this kind, although systematic researches in malaria have not been made largely because of the impossibility of securing adequate numbers of the parasites for studies of this kind. But available data indicate that quinin does not increase the production of the antihemolysins for the malarial hemotoxin and I personally doubt if quinin cures malaria by any mechanism of this kind.

Bass and Johns have observed that normal serum is toxic for the plasmodia *in vitro* and have suggested that quinin destroys the parasites by increasing the permeability of erythrocytes for toxic constituents of the plasma. This interesting theory requires confirmation and a mechanism of this kind may, indeed, exert some rôle in the antiplasmodial properties of quinin, but the drug is apparently capable of destroying the young asexual parasites free in the plasma which rather indicates a direct plasmodocidal effect rather than a mechanism increasing the normal toxicity of the plasma.

It is also probable that quinin may reduce the oxidases of the plasma and that this may interfere with the life processes of the plasmodia, but so far there is no direct evidence of this mechanism playing any important rôle in the plasmocidal activity of quinin, although, as discussed in Chapter XXIII, it is believed that the trypanocidal and spirocheticidal properties of the organic arsenicals and the protoplasmic toxicity of arsenic in general may be due to an interference with the processes of oxidation and reduction, that is, the so-called internal respiration of cells.

Whether quinin is less effective against the schizonts and merozoites or full grown intracorpuscular parasites of all types and especially weak in parasitocidal activity for the sexual forms or gametocytes of all types, cannot be stated. It is believed by some that the gametocytes are formed only when the parasites are placed in adverse conditions, as in the presence of small subcurative amounts of quinin, and that they correspond to the spore stage of some of the bacteria as an expression of self-preservation; but be this as it may, the fact remains that these sexual forms are far more resistant to destruction directly or indirectly by quinin than the asexual forms.

Quinin Fastness in Relation to the Prophylaxis and Chemotherapy of Malaria.—Furthermore, it is well established that the malarial plasmodia and especially *P. falciparum* may occasionally acquire varying degrees of resistance or fastness to the plasmodocidal effects of quinin and it is believed that this may account for the difficulties encountered in the treatment of some cases of chronic malaria and especially of aestivo-autumnal fever. The evidence in favor of the acquisition of this state, however, is almost entirely clinical. But there are no reasons for doubting that plasmodia may acquire a resistance to quinin, just as trypanosomes have been rendered resistant to some of the dyes and organic arsenicals, although resistance to quinin in any given case of malaria may be due rather to the presence of sexual forms (gametocytes) of the parasites in the blood and tissues, which are known to be resistant to quinin, without actual acquired quinin-fastness. Moreover in not a few cases of chronic malaria resistant to quinin it has been found that this state was not due to an acquired fastness of the parasites, but rather to the fact that the patient was not actually swallowing the drug or because of gastric disturbances with or without vomiting which interfered with absorption. Indeed, when these factors have been adequately controlled, the number of cases of true quinin resistance have been greatly reduced and confined almost entirely to *P. falciparum* (aestivo-autumnal) infections. One of the most recent experiences showing the importance of first ruling out the matter of absorption before concluding that "quinin-fastness" existed, have been recently reviewed by Fletcher:[16] In 1917, reports began to appear that English soldiers in the tropics were being attacked by malaria that quinin would not cure. Pratt-Johnson and Gilchrist found that relapses were reported in 23 per cent. of 18,000 soldiers in Africa, while quinin was being administered Phear reported in Macedonia that quinin was ineffective in malaria that was complicated by dysentery. Willcox in Mesopotamia encountered cases that did not improve under quinin by mouth for ten days. Mackie found quinin ineffective in malaria in northern Persia, and the accumulation of invalids in Saloniki was constantly increasing. Such contradiction and disappointment concerning quinin led to an extensive experimental and clinical inquiry into the treatment of malaria at the Liverpool School of Tropical Medicine, the results of which, unfortunately, did not entirely restore confidence in quinin.

Many soldiers were sent back to England from Macedonia in 1918, and Sir Ronald Ross arranged to treat the malaria patients in special wards at Southampton. Fletcher states that 1150 patients were admitted to these wards in twelve months, and that on landing, parasites were found in the peripheral blood in 487. Although many had documentary evidence of treatment with quinin in various hospitals, they were placed on 10 grains of quinin by mouth twice a day. There was strict supervision of these patients, and special interest in relapses that might occur. In every instance the routine treatment prescribed at Southampton caused both fever and parasites to disappear.

Fletcher emphasizes the Southampton experience by a report of his observations in the Federated Malay States since the war. The patients seen there were little more than skeletons, and dysentery was a complication in 53 per cent. Forty-four difficult cases in which quinin had been disappointing were selected, and 10 grains of quinin by mouth twice a day was given for four weeks. The drug was placed in the patient's mouth by the physician, and, after it had been swallowed, the mouth was inspected. Not one of these coolies in Kuala Lumpar failed to improve. There was in one a small number of parasites that persisted in the blood in spite of quinin, but in every other case, both fever and parasites disappeared. Dysentery did not make any difference. When quinin was actually swallowed and retained, malaria in dysentery patients was as easily controlled as in patients who did not have dysentery. The conclusion of this study was the same as among soldiers in Southampton, namely, that the so-called resistance to quinin vanished when the quinin was actually swallowed and retained.

In general, Fletcher's report is a plea for the restoration of faith in quinin in malaria, and for its oral administration. He does not say that an absolute resistance to quinin is impossible, but in a wide experience he had not seen one case of actual resistance.

However, actual quinin resistance may be apparently acquired and especially in *P. falciparum* infections, but the mechanism involved is still obscure. At least, the Ehrlich theory of chemoreceptoric atrophy would appear to be insufficient and unsatisfactory, as already discussed in earlier chapters. The parasites are apparently capable of immunizing themselves against the effects of quinin, but just how they do this is unknown. It is of considerable practical value and theoretical interest to note, however, that parasites resistant to the salts of quinin may be susceptible or vulnerable to cinchonin or other alkaloids of Peruvian bark.

Quinin-fastness also bears an important relation to the prophylaxis of malaria in this manner, that the taking of quinin by chronic cases may result in a state of fastness of the parasites which may be capable of transmitting this state to new generations after undergoing the sexual cycle in the body of anophelines. If this were possible, it may be that in malarial districts, quinin-resistant strains of the various plasmodia are propogated. We at least know that trypanosomes rendered resistant to the dyes and arsenicals are capable of transmitting this state indefinitely, but I am not cognizant of any experiments showing whether a resistant strain of *T. gambiensi*, for example, is capable of transmitting this quality after passage through the tse-tse fly or whether quinin-resistant strains of malarial plasmodia are capable of maintaining and transmitting this quality after passage through anophelines. It is entirely likely, however, that such is possible and if so, the importance of protecting the chronic malarial and possibly quinin-resistant cases against mosquitoes is indeed a doubly important matter and worthy of investigation.

Methylene-blue in the Chemotherapy of the Malarial Fevers.—This dye (tetramethyl-thionin hydrochlorid) was introduced by Ehrlich and Guttman for the treatment of malaria on the basis of its selective coloring properties and especially for the treatment of those cases to whom adequate doses of quinin could not be given. Especially good results were claimed in *P. malariae* (quartan) fevers, although some effects were also noted in *P. vivax* (tertian) and *P. falciparum* (aesitivo-autumnal) fevers. Since then, a rather large literature has accumulated upon the subject and with the discovery of the trypanocidal activities of some of the dyes, interest was greatly renewed, but recent studies in malaria with trypaflavin and tryparasan by Kalberlah and Schlossberger[18] and others have shown that these new synthetic dyes are lacking in antimalarial properties.

Methylene-blue, however, in dose of one gram (15 grains) per day by ingestion, is well borne and appears to be worthy of trial in the treatment of chronic malaria along with the administration of quinin and especially in those cases in whom the plasmodia appear to have acquired a fastness or resistance to these compounds; as stated by Reitter,[19] methylene-blue alone is ineffective, but is frequently of aid when given with quinin in the treatment of rebellious cases and especially in aestivo-autumnal fever. Just how or why this should be so I am unable to state. The dye itself is but feebly plasmocidal and probably owes its helpful effects in malaria to an interference with the internal respiration of the parasites by processes of alternate oxidation and reduction. It is likely that quinin owes part of its plasmocidal activities to an interference with the oxidases of plasma and I surmise that the two compounds act synergistically in this manner and thereby aid each other in the destruction of crescents and other quinin-resistant types of the plasmodia.

Arsphenamin and Other Arsenicals in the Chemotherapy of the Malarial Fevers.—With the discovery of the trypanocidal and spirocheticidal properties of atoxyl, arsacetin, arsenophenylglycin and finally of arsphenamin and

neoarsphenamin, it is no wonder that these compounds should have received early trial in the treatment of the malaria fevers and a rather large literature has accumulated upon the use of two latter compounds. It is now well known that the administration of arsphenamin or neoarsphenamin may stimulate cases of chronic latent malaria into activity sometimes with fatal results, as reported by Huck and Bowden,[20] Sklarz,[21] Bernard,[22] Milian,[23] Goresco and Popesco[24] and others. In some cases this has aided in finding the organisms in the blood and establishing the diagnosis.

Arsphenamin was apparently first used by Iversen and Nocht in the treatment of malaria in 1911 and since 1912 a rather large literature has accumulated on the subject with conflicting opinions of its value in the treatment of the disease. Among the early reports, all of which were favorable, may be mentioned those by Werner,[25] Tuschinsky,[26] Ivananoff,[27] Bogan,[28] Reed[29] and Goldthwaite.[30] Falconer Anderson[31] observed good results with arsphenamin and neoarsphenamin along with quinin in the treatment of tertian and quartan fevers, but not in aestivo-autumnal fever; quinin and galyl also yielded good results. Stephens, Yorke and Blacklock,[32] Stott,[33] Neff[34] Manson,[35] Teubern,[36] D'Esterre,[37] Surbek,[38] Bohme[39] and others have reported that arsphenamin and neoarsphenamin are sometimes useful adjuvants to quinin and especially in the treatment of chronic quartan and tertian infections. Marchouix[39a] found the internal administration of *stovarsol* efficacious in tertian malaria in dose of 1 gram several times a day.

However, others claim that arsphenamin and its substitutes are without beneficial effects and may even prove harmful. Thus, Kopanaus,[40] in 1911, although observing some beneficial results in the treatment of tertian fever in man from the administration of arsphenamin, made a very thorough stuy of its effect on proteosoma, an organism producing bird malaria, and found that the drug, in large and small doses, actually lowered the resistance of the birds to the organism without being in itself curative. Kalberla and Schlossberger[41] did not observe any direct plasmodicidal effects of arsphenamin, neoarsphenamin or silver arsphenamin; Stephens[42] states that neoarsphenamin in conjunction with quinin is no more effective than quinin alone in aestivo-autumnal fever and Worner,[43] while considering neoarsphenamin useful for general treatment and for correcting the anemia, states that it is of no value for the treatment of gametocyte carriers.

These clinical reports indicate, therefore, that arsphenamin, neoarsphenamin and possibly stovarsol may possess a slight degree of parasitropism for the plasmodia of the malarial fevers of man and especially for *P. malariae* (quartan) and *P. vivax* (tertian), but these direct destructive effects are very much less than exhibited by quinin. For the sexual organisms or gametocytes of all three species, these compounds are ineffective, but quinin is likewise of greatly reduced parasitotropic effects for these. In acute early malaria, therefore, arsphenamin and neoarsphenamin alone are very much less effective than the salts of quinin and should not be given unless the latter compounds cannot be administered on account of allergic hypersensitiveness. In chronic malaria, however, and especially in quinin-resistant cases, it would appear that arsphenamin, neoarsphenamin and sulpharsphenamin are useful adjuvants to quinin, not so much by a direct plasmodocidal activity as by some mechanism tending to bring the parasites into the circulating blood, where they become more vulnerable to quinin. Furthermore, the arsenicals tend to correct the anemia of malaria and improve the metabolism and nutrition, especially of chronic cases; this is true, however, of the inorganic arsenical compounds as well, which have long enjoyed a place in the adjuvant treatment of the disease.

How arsphenamin and its substitutes aid in the specific treatment of malaria is not known. According to some observers the organic arsenicals increase the ameboid movements of the parasites and thereby bring them out into the circulating blood. In my opinion, the effects are rather due to the vasodilating properties of arsphenamin and its substitutes with the result that the parasites in corpuscles in the capillaries are dislodged. However that may be, there is no doubt that the compounds may produce Herxheimer-

like reactions in malaria and thereby aid in both diagnosis and treatment of chronic, latent infections. In addition, it is probable that the arsenic of these compounds interferes with the processes of oxidation and reduction, that is, the internal respiration of the parasites as originally claimed by Binz for explaining the toxicological effects of arsenic in general for protoplasm. Arsphenamin and neoarsphenamin, however, may combine with the malarial plasmodia through the affinity of the arsenic for sulphur compounds in the protoplasm of the parasites and bring about their destruction in a manner analogous to the mechanism involved in trypanocidal activity. However, if this is true, it would appear that the plasmodia contain much less sulphhydril compounds than trypanocomes and spirochetes, because the parasitropic effects are so much less for the former.

Quinin Prophylaxis of the Malarial Fevers.—In the prophylaxis of the malarial fevers most has been accomplished by antimosquito protection and the destruction of the pests, combined with the administration of quinin. There is no doubt of the efficacy of quinin prophylaxis, although in the malarial districts it is difficult and expensive to apply on a large scale and the prolonged ingestion of the drug tends to produce nervous irritability and tremors in some individuals. The advantages of quinin prophylaxis, however, are in excess of the disadvantages, and the practice has been strongly and universally recommended. Various methods or plans have been proposed, among which may be mentioned the following:

(*a*) Koch's method, which consists in taking 15 grains on two consecutive days every eight or ten days for three months.

(*b*) Celli's method, which consists in taking about 6 grains daily.

(*c*) Plehn's method, which consists in taking 8 grains every fourth day.

(*d*) Castellani and Chambers give 5 grains daily with a double dose or 10 grains every Sunday. For children 1 grain of quinin may be given for every three years of age, or euquinin in daily dose of 2 to 5 grains in a little sweetened milk, as advised by Celli, may be administered. In very malarious zones, such as certain tropical countries and the Balkans, they recommend larger doses than those advised above.

Since 0.1 to 0.2 gm. (2 to 3 grains) is usually sufficient for temporarily cleansing the blood of asexual forms of plasmodia, it would appear to me that the method of Castellani and Chambers is to be recommended, except that the dose may be reduced to 2 or 3 grains daily when the district is not very malarious and when the drug is to be taken over months and years of time.

Celli has estimated that in certain districts of southern Europe about 33 per cent. of the population developed malaria when no prophylactic measures of any kind were taken. Quinin prophylaxis alone reduced the incidence to 20 per cent.; antimosquito protection alone reduced it to 2.5 per cent., while quinin prophylaxis and antimosquito protection reduced it to 1.75 per cent.

Advantages and Disadvantages of Various Methods for the Administration of Cinchona Alkaloids in the Treatment of Malaria. *Method of Ingestion.*—Owing to rapid absorption of quinin from the stomach and intestines (especially the former) when these organs are in good condition, the oral administration of quinin has been long the favorite method of treatment and is undoubtedly of most value for the routine treatment of the malarial fevers except in very severe or malignant cases when intravenous injections may be required to bring the disease under control. But oral administration may be contra-indicated in some cases and possesses certain disadvantages. The bitter taste of quinin may be objectionable, but this can be usually overcome by administering the more soluble salts in chocolate covered tablets,

capsules or cachetes and for children the less bitter euquinin or quinin tannate may be given in capsules or cachetes or suspended in chocolate syrup or some other sweetened vehicle.

In cases of coma and vomiting the method of ingestion may not be advisable or possible, in which case intramuscular or intravenous injections may be required.

Furthermore, in vomiting the contents of the stomach may be rendered alkaline by the bile, in which case the absorption of quinin is hindered or fails to occur; under such circumstances, it may be first necessary to cleanse the stomach, and my colleague Dr. Yardumian, who has had an exceptionally rich experience in the treatment of malaria in Armenia and Turkey, states that hypoacidity or anacidity of the stomach and especially bilious vomiting with neutralization of the gastric juice, constitute very important reasons why quinin by ingestion may fail to cure malaria, although he believes that the method of ingestion is in the one of choice for the administration of the drug when these conditions receive appropriate attention and treatment and when the patient may be relied upon to actually swallow the drug or when it is possible to administer it under the supervision of a nurse or physician to prevent deception.

A large number of quinin preparations have been advocated for the treatment of malaria by ingestion. The sulphat is the cheapest, but probably the least desirable on account of being so lightly soluble (1:725) except in an acid medium. For adults whose stomachs are in good condition, the bisulphate or dihydrochlorid may be given in freshly prepared capsules. It is imperative, however, that old and hardened capsules, pills and tablets be avoided because of the possibility of these not dissolving and being absorbed. If the acidity of the gastric juice is reduced, it is advisable to use solutions. If the sulphat is employed, it is necessary to use about one minim of either sulphuric or hydrochloric acid for each grain for purposes of rendering it soluble, with the addition of some vehicle to aid in disguising the bitter taste, the following formula being satisfactory;

Quinin sulphatis	℥IV (15 gm.)
Acidi sulphurici dil.	℥V (20 c.c.)
Syr. aurantii cort.	℥I (30 c.c.)
Aq. Distil.	q.s.ad ℥iii (100 c.c.)
M. Dose 1 teaspoonful or 4 c.c.	

The bisulphat is much better, being acid and more soluble (1:9); likewise the dihydrochlorid, which is soluble 1:0.6.

Method of Intramuscular Injection.—This route of administration is always advisable when the patient cannot or will not swallow and in cases of severe vomiting. It is a mistake, however, to assume that absorption from the muscles may be more rapid than from the stomach. Fletcher, previously quoted, has recently stated that in Kuala Lumpus he gave 10 grains of the dihydrochlorid dissolved in 22 minims of salt solution to 22 patients by intramuscular (gluteal) injection. The shortest time that quinin appeared in the urine was twenty minutes and the average time was sixty minutes; the same amount of drug given by mouth was followed by the appearance of quinin in the urine in fifteen minutes, with an average of thirty-one minutes. He states that regardless of the alkaloid employed and its concentration, intramuscular injection is always followed by some degree of necrosis which in some cases may develop into an abscess. Furthermore, that large nerves may be involved, with great pain and at least temporary paralysis. He quotes Sir Patrick Manson as opposed to this route of administration except

for good reasons, and also states that Sir Ronald Ross had repeatedly declared himself against this route for the treatment of ordinary cases.

However, there are times and cases when intramuscular injections are indicated and required and I know that my friend S. Solis-Cohen has given quinin and urea hydrochlorid by intramuscular injection in the treatment of a large number of cases of malaria and pneumonia since 1893 with uniform success. His method consists in thoroughly sterilizing the water and syringe (all-glass preferred) and carefully preparing the skin by washing with soap and water and applying a coat of tincture of iodin. The drug (15 grains ordinarily) is dissolved in 2 to 5 c.c. of boiling water (20- to 50-per cent. concentration) and after cooling is injected deeply in the muscles, care being exercised to empty completely the syringe before withdrawal of the needle to avoid depositing any of the drug in the subcutaneous tissues. The iodin is then removed with alcohol and the puncture sealed with flexible collodion.

Some pain usually follows the injection, but I have prevented this in many instances by incorporating into the above solution 0.5 c.c of a sterile 1-per cent. solution of novacain or butyn. The following solution is also said to be less painful: 10 grams of quinin hydrochlorid and 5 grams of ethylurethane dissolved in 20 c.c. of distilled water, followed by sterilization. Each cubic centimeter contains approximately 0.5 gm. of quinin and the dose is ordinarily 2 c.c. or about 1 gm. (15 grains). It is always advisable, however, for physicians practicing in malarial districts to keep ampules of a sterile solution of quinin on hand and these are made available in splendidly prepared solutions by various commercial laboratories. Recently Macphail[43a] has again emphasized the value of intramuscular injections of 15 to 22½ grains of quinin dihydrochlorid in the treatment of serious cases of malaria and it would appear that this route of administration has the approval of many experts practicing in malarial districts.

Method of Intravenous Injection.—The intravenous injection of the cinchona alkaloids is accompanied by considerable danger and is certainly not to be regarded as a method of choice, but rather one of necessity to meet urgent situations. The sudden introduction of these compounds and especially concentrated solutions by syringe injection, which are so frequently described in text-books, may produce a great reduction of blood-pressure by cardiac depression and vasodilatation through peripheral action and it is particularly important to avoid this route of administration if the patient presents signs and symptoms of cerebral malaria, as the vasodilating effects of the meningeal vessels and depression of the respiratory center may be fatal. Likewise, when there are evidences of cardiac weakness or distress, great care is required and not infrequently in cases of pernicious malaria in which one is most tempted to use this route of administration, the blood-pressure is generally low, anyhow, on account of the infection. Furthermore, intravenous injections tend to produce distressing tremors and respiratory distress, and accidental perivascular infiltrations may produce local necrosis and sloughing.

However, against these dangers is the unquestionable rapidity with which the drug is brought in contact with the parasites in the blood, and Cantile and Moubarak[44] and others believe the method particularly indicated for the hospital treatment of malaria, since the maximum in results are obtained in the minimum of time. According to Maxcy,[45] its proper field of usefulness seems to be upon urgent clinical indications of two sorts: first, in cases in which prompt absorption by the gastro-intestinal tract, following mouth administration, is not to be expected, because of violent gastro-intestinal disturbance or other cause, or in which it is impossible to give the drug by

mouth on account of delirium, coma, etc; and second, in cases which are gravely ill when first seen by the physician and in whom it is deemed imperative to secure immediate cinchonization. It does not seem necessary or desirable to use the intravenous route of administration in the simple acute or chronic infections ordinarily encountered, whether tertian or aestivo-autumnal, because there is no clear evidence at present that in ordinary malarial infections the method is more effective than mouth administration in curing an acute attack, in ridding the blood of sexual forms, or in preventing relapse.

Both Maxcy and more recently Brahmachari[46] have emphasized the necessity of giving dilute solutions and injecting them slowly. The latter has studied the influence of injections of concentrated and diluted solutions on blood-pressure with interesting results. The injections were given in the apyrexial period, except in one case. He observed that the intravenous injection of quinin in concentrated solution (10 grains in 20 c.c.) was generally followed by a fall in blood-pressure and may cause a disappearance of the pulse for a few seconds. Intravenous injection of quinin in dilute solution (10 grains in 200 c.c.) might be also followed by a fall in blood-pressure, but this fall was neither as sudden nor as great as when the solution was concentrated; in many cases there was no reduction at all. The more slowly the injection was given the less likely was there to be a fall of blood-pressure. The diminished blood-pressure may persist for twelve hours or more after the injection. The author states that the intravenous injection of quinin should always be given in very dilute form (1:300) at the rate of 10 c.c. every minute and that it should never be undertaken lightly.

The dihydrochlorid is the salt generally employed. The dose is ordinarily 1 gram (15 grains) and this should be dissolved in at least 100 c.c. and preferably 200 c.c. of warm sterile, physiological saline solution and injected slowly by gravity in exactly the same manner as the intravenous injection of arsphenamin. It is well to watch the pulse and respiration very carefully and better still, to have the blood-pressure taken at intervals during the injection. It is also a good practice to have in readiness a syringe containing 1 c.c. of 1:1000 adrenalin chlorid: and in case of circulatory collapse, 0.1 or 0.2 c.c. of the solution may be injected into the quinin solution through the rubber tubing for intravenous administration or 0.5 to 1 c.c. may be injected intramuscularly. If the patient is hemorrhagic, that is, purpuric or passing blood or hemoglobin through the kidneys, it is well to dissolve the quinin in 100 c.c. of 0.5-per cent. solution of calcium chlorid in saline solution and inject the two drugs together, as will be discussed shortly with more detail in the treatment of blackwater fever.

While, however, the intravenous administration of dilute solutions by syringe injection appears to be the method of choice, it is well known that in practice it cannot always be applied and especially in the country districts. Furthermore, concentrated solutions have been injected too frequently and successfully to condemn the method. Bass, for example, has described a method consisting of dropping two 5 grain tablets of quinin dihydrochlorid in the barrel of a 20 c.c. syringe carrying a few cubic centimeters of sterile saline solution and, after dissolving, filling to the 20 c.c. mark and injecting. Castellani and Chambers described the injection of 15 grains of the same drug dissolved in 5 to 10 c.c. of saline solution. But if these methods are employed, the injection should be given slowly by means of a small needle like No. 22, in order to have thorough dilution with the blood.

Method of Rectal Injection.—Quinin is ordinarily so irritating to the rectum that this route of administration is of very little value. When the drug cannot be given by stomach, intramusclar injections are to be preferred.

If rectal administration is attempted, 20 grains of the dihydrochlorid may be dissolved in 3 ounces of starch solution containing a few drops of tincture of opium and injected as high as possible. Suppositories of quinin or quinoform may be employed in children.

General and Specific Treatment of Acute Malarial Fevers.—A very large number of plans or methods for the treatment of malaria with quinin have been proposed, different authors placing varying importance upon many factors, as the time when the drug should be given in relation to the paroxysms, the particular drug to use, the dosage, route of administration, etc. All of these are worthy of consideration since they are influenced by the kind of infection, its severity and duration, so that no hard and fast rules are permissible.

1. It is always advisable to examine the blood for the kind or kinds of plasmodia present and the proportion of infected corpuscles; for example, when 5 per cent. of cells are carrying parasites, it is apparent that a severe infection exists requiring intensive medication.

2. Calomel should be administered followed by a saline. In some unaccountable manner this drug appears to favor the absorption and activity of quinin. The heart should be examined and if weak or irregular with a weak pulse and low blood-pressure, due care must be exercised in the dosage and route of administration of quinin. Stimulants like 1 to 3 grains of caffein citrate by ingestion or subcutaneous injection may be indicated. In pregnancy, due attention must be given to the possible effects of quinin on the uterus and smaller doses than usual given in order to minimize the danger of exciting contractions. Sodium bromid in dose of 5 grains once or twice a day may be advisable for excitability or nervousness due to quinin or the infection.

3. For benign tertian and quartan fevers of adults, 10 grains of quinin bisulphate may be given three times a day or 15 grains twice a day until the temperature has been normal for a week or ten days. In severe tertian and quartan fevers and in all cases of pernicious malaria (aestivo-autumnal fever), it may be necessary to give 15 to 20 grains three times a day or to give one intramuscular injection of 15 grains of the dihydrochlorid or quinin and urea hydrochlorid and three 10-grain doses by ingestion per day until the infection is under control. In pernicious malaria daily intravenous injections of 10 to 15 grains of the dihydrochlorid may be required for the first three to five days, these being omitted and intramuscular injections substituted until the infection is brought under control; at the same time the bisulphat may be given orally in dose of 10 grains three times a day.

4. In typical malaria when the patient is first seen in an acute attack, the first dose of quinin may be given during the crisis when the fever is declining in order to attack the merozoites free in the blood or shortly after they have entered corpuscles.

5. Quinin may be given as described until the infection is under control; by this I mean the absence of fever and chills for at least seven to ten days along with negative blood smears.

6. From this time on 10 grains may be given twice daily for the first month, 10 grains once daily for the second month and 5 grains once daily for the third month; or the method advised by Rivas may be employed: 10 to 15 grains twice a day for three days in succession followed by a four day interval without quinin, these periods alternating for two or three months, followed by 10 grains daily for the balance of the season.

7. Certain symptoms may require special measures. *Headache*, for example, may require cold applications to the head; the coal tar products

like phenacetin and acetanilid should be avoided if possible. *Hyperpyrexia* is relieved by cold sponging. After the sweat it is well to change the clothes and give a sponge bath with alcohol or tepid water. *Vomiting* may be relieved by sips of iced water, limeade, etc., but if it continues the stomach should be washed out. It must not be overlooked that in the presence of vomiting, quinin may not be absorbed and that intramuscular injections may be required. During the *chills*, hot water bottles and blankets may be required. *Coughing*, *hiccough* and *diarrhea* may require appropriate treatment. In severe malaria, as in cases with cerebral symptoms, algidity, severe choleraic diarrhea and vomiting, scarlatiniform rashes, etc., indicating a high degree of toxemia, it is advisable to give intravenous injections of 500 to 800 c.c. of physiological saline solution; if these cannot be administered, it is advisable to inject the saline under the skin. These injections frequently yield splendid results and especially if free sweating occurs; they may be repeated once or twice daily. In hemorrhagic cases with purpura or hemoglobinemia and hemoglobinuria, it is well to add 0.5 to 1 gram (8 to 15 grains) of calcium chlorid to the saline for injection intravenously or subcutaneously and 0.5 to 1 c.c. of 1:1000 adrenalin may be injected subcutaneously if the heart and pulse are weak with low blood-pressure.

8. During the acute attacks the diet should be light and of fluids; in the asymptomatic periods and convalescence ordinary food may be given.

9. During convalescence it is necessary to see that the patient's bowels are evacuated once daily and a simple "tonic" mixture of iron and strychin may be useful.

General and Specific Treatment of Chronic and Relapsing Malarial Fevers.—It is frequently a very difficult matter to determine when malaria is completely cured in the sense of total extirpation of all plasmodia, and, indeed, if the disease has been present for several months before treatment has been begun, it is impossible to determine when complete cure has been obtained, since negative blood smears may be observed in cases in which parasites are lodged in the spleen and other organs. When the disease has been present for years these difficulties are greatly increased and complete cure frequently impossible, although relapses may be successfully combated by quinin therapy.

1. It is important to correct constipation and if chronic gastro-intestinal disturbances are present, possibly associated with hypoacidity of the gastric juice, it is advisable to administer the acid salts of quinin like the bisulphat or hydrochlorid, and their solution and absorption may be aided by giving 10 minims of dilute hydrochloric acid in water with each dose.

2. Relapses may be treated with quinin as described above for the specific treatment of acute malaria, but since these cases are particularly apt to develop an intolerance for the drug, it is well to treat rather intensively for a week at a time alternating with periods of a week without quinin. In other words, it would appear that the correct principle is to "hit hard" for a short period rather than lightly over a prolonged period. If intolerance is present, it is sometimes possible to administer one of the salts of cinchonin. For these cases with extreme quinin hypersensitiveness, it may be necessary to attempt desensitization.

In addition, it may be helpful to give 5 grains of methylene-blue in capsules three times as day; picric acid in dose of 2 grains two or three times a day by ingestion has also been recommended.

I am convinced that the intravenous injection of 0.4 gm. of arsphenamin or 0.6 gm. of neoarsphenamin is frequently helpful and these injections, especially of neoarsphenamin, may be repeated at weekly intervals until

the infection is again under control, as indicated by freedom from signs and symptoms with negative blood smears for at least a period of ten days. Furthermore, injections of neoarsphenamin are quite helpful for aiding in the treatment of malarial anemia and cachexia, as discussed with more detail in Chapter XXXIV.

Chemisse[47] believes that the internal administration of 5 to 10 drops of tincture of iodin, well diluted with cinnamon water, twice daily, should be given with the quinin; possibly the iodids may be substituted for the iodin.

3. After a relapse has subsided, it is well for the patient to take quinin periodically for months or years of time. But in order to reduce the chances of gradually evolving a quinin resistant strain, it would appear advisable to adhere to some plan whereby 5 to 10 grains are taken once a day for five to seven days every month rather than smaller doses more or less continuously. Of course, this is greatly influenced by the degree of infection and the tendency for relapses, but the principle of "hitting hard" for a short time with relatively large doses appears to be correct, both from the standpoint of controlling the infection and of avoiding the muscular tremors and other signs of chronic cinchonism.

As previously stated, it is impossible to determine when a complete cure has been effected, but, according to Thaller,[48] Habetin[49] and others, the intramuscular injection of sterilized milk in dose of 5 to 10 c.c. or subcutaneous injection of nucleic acid or sodium nucleinate sometimes provokes latent infections and brings the parasites into the blood stream where they may be detected by smear examinations.

According to Silvestri,[50] Schimert[51] and others, the intramuscular injection of milk and other agents, including intravenous injections of the patient's own serum, frequently aids treatment with quinin in chronic resistant cases.

4. In *chronic malaria with hemoglobinuria*, large doses of quinin are required since there are usually *P. falciparum* infections. But it is well to precede the quinin by one or two intravenous injections of 5 c.c. of a sterile 5-per cent. solution of calcium chlorid in water or saline and these may be given once a day for several days to control the hemorrhage; the injections must be given *very slowly* and with great care. Or calcium lactate in dose of 5 to 10 grains may be given by mouth before and during quinin administration.

5. As previously stated, I believe that the so-called *quinin hemoglobinuria*, sometimes developed by cases of chronic malaria, is really due to malarial infection. Sometimes it is sufficient to give 10 grains of calcium lactate by mouth before each dose of quinin, but if this fails it is usually possible to control the bleeding by the intravenous injection of 5 to 10 c.c. of sterile 5 per cent. solution of calcium chlorid once a day for three days while quinin is being administered to check the infection.

6. *Blackwater fever* is a far more serious manifestation of chronic malaria, calling for more vigorous treatment. It is advisable first to check the bleeding and flush out the kidneys and for this purpose 100 to 200 c.c. of a sterile 0.1 per cent. solution of calcium chlorid in physiological saline should be injected subcutaneously or intravenously (*slowly*) once or twice a day. After the first injection or two, quinin may be given and preferably in the form of an intramuscular injection once daily of 10 grains of the dihydrochlorid or quinin and urea hydrochlorid. If there is no vomiting, calcium lactate may be given orally in dose of 5 grains two or three times daily, and Castellani and Chambers also recommend the oral administration of the following Sternberg-Hearsay mixture in dose of one ounce every two to four

hours during the first twenty-four hours and then every three hours until the urine clears:

Liq. hydrargyri perchloridi			f℥III(12 c.c.)
Sodii bicarbonatis			℥I (4 gm.)
Aq. distil.	q.s.	ad	f℥vi (200 c.c.)

However, vomiting may be present and prove so troublesome as to require small doses of morphin and atropin. As a general rule, it is advisable to administer calomel followed by a saline at the onset of the attack, but if diarrhea supervenes, bismuth may be required.

The heart must be carefully watched and stimulated if required by digitalis or caffein. When quinin is administered, it may be necessary to give intramuscular injections of 0.5 to 1 c.c. of 1:1000 adrenalin to correct vasodilatation and intramuscular or subcutaneous injections of pituitrin (1 c.c.) have also been recommended.

Headache and hyperpyrexia are best treated with cold applications and bathing, since it is advisable to avoid drugs as much as possible.

Anuria always threatens in severe cases and the kidneys must be relieved by promoting the activity of the skin by hot wet packs and by free purgation. The backache may be relieved by dry cupping or hot fomentations, but if these fail, small doses of morphin may be required.

The patient should be encouraged to take plenty of water or lemonade, but if vomiting is present, dehydration and thirst should be corrected by subcutaneous or intravenous injections of calcium-sodium-chlorid solution aided by rectal infusions of saline. The Murphy drip method is sometimes useful for this purpose. The diet should be of fluids and as nutritious as possible.

7. Whenever possible it is advisable for chronic malaria cases to seek a change of residence to colder climates and this is especially advisable for those who have had attacks of malarial or quinin hemoglobinuria or the severer blackwater fever. A return to the tropics is always fraught with much danger.

CHAPTER XXXIII

CHEMOTHERAPY OF LEISHMANIASIS, AMEBIASIS, PIROPLASMOSIS, SCHISTOSOMIASIS AND OTHER PROTOZOAN AND METAZOAN DISEASES OF MAN AND THE LOWER ANIMALS

As stated in the preceding chapter, our present knowledge of the specific treatment of protozoan and metazoan diseases of man and the lower animals, with the exception of these caused by trypanosomes and spirochetes, is almost entirely confined to clinical experience with certain drugs, rather than the result of systematic chemotherapeutic investigation. In not a few diseases caused by protozoa, however, and especially the various forms of leishmaniasis like kala-azar and oriental sore, the antimonyl salts and particularly tartar emetic act almost as specifics; and likewise in some of the metazoan infestations, as in the different types of schistosomiasis, these compounds possess a high degree of curative activity, so that they have as much right to be classed with the group of specifics and in the field of chemotherapy as the cinchona alkaloids in the treatment of the malarial fevers.

In this chapter, I wish to consider the remainder of those diseases caused by protozoa and metazoa in which a more or less specific therapy may be said to exist; I do not doubt that the curative activity of tartar emetic, emetin hydrochlorid and other compounds to be considered could be improved upon by orderly and systematized chemotherapeutic research and especially for those diseases transmissible to the lower animals which always offers

thereby a way and stimulus for experimental investigations. But before taking up the subject of treatment, it may be well to consider some of the more important pharmacological and toxicological properties of the antimonyls and of ipecac and its alkaloids.

Chemistry, Pharmacology and Toxicology of Antimony Compounds in Relation to the Chemotherapy of Protozoan and Metazoan Diseases.—While the toxicity, trypanocidal and spirocheticidal activity of antimony and potassium tartrate (tartar emetic), as well as some new compounds like sodium antimony thioglycollate and the triamid of antimony thioglycollic acid (antimony thioglycollamide) prepared by Abel, have been already discussed in earlier chapters, yet it may be of interest to discuss here the absorption, elimination and certain other pharmacological actions of antimony, as well as the toxicological effects for human beings, inasmuch as tartar emetic is used so extensively for the treatment of protozoan and metazoan infestations.

Chemistry of Antimony Compounds in Relation to Toxicity and Therapeutic Activity.—Tartar emetic has been mostly employed and but comparatively little work has been done on new antimonyls, but the results have indicated that some of the new compounds may be superior and this is highly desirable since it is quite apparent that tartar emetic is not by any means the ideal or satisfactory remedy for kala-azar and other forms of leishmaniasis, largely because of its toxicity and the intolerance developed by many individuals requiring a long series of injections. In Chapter XIII, I have already referred to the work of Rowntree and Abel, and Voegtlin and Smith, who have prepared new pentavalent and trivalent organic compounds of antimony, some of which were apparently superior to tartar emetic in the sense of being less toxic for the host while possessing a high degree of parasiticidal activity. Mention may also be made of the work of Fargher and Gray[1] who have studied the effect of variation of the basic radicle in the emetics, the replacement of tartaric acid by other suitable acids and the question of the relative merits of the true organic compounds of antimony and the emetics. The general conclusion was drawn that a variation in the base in the antimonyl tartrates considerably reduces the toxicity per unit of antimony, the most favorable salts being those of quinin and p-phenetidin, but the replacement of tartaric acid by other acids yielded little of pharmacologic interest. As shown by Brunner[2] in 1912, trivalent organic compounds are more toxic than pentavalent compounds, being similar in this respect to the organic arsenical compounds, and it may be recalled that Kolle and his associates, as well as Voegtlin and Smith, found that trivalent antimonyls, while more toxic for the host were likewise more trypanocidal and more rapid in effects than the pentavalent compounds.

Brahmachari[3] has more recently reported interesting studies upon the comparative toxicity of the antimonyl tartrates and some new aromatic compounds. Ammonium antimonyl tartrate was found to be the least toxic of all the tartrates, the presence of nitrogen in the basic radicle diminishing the toxicity of some of these compounds. Because of the high antimony content of the ammonium salt, its relatively low toxicity for the lower animals and likewise for human beings, and since it was found to possess a marked degree of therapeutic activity in the treatment of kala-azar, Brahmachari considers it superior to both potassium and sodium antimonyl tartrate. But some of the new organic aromatic antimonyls and particularly urea stibamine, were found less toxic and equally useful in the treatment of kala-azar. In addition to this compound he has described the preparation and toxicity of (1) phenyl stibinic acid; (2) acetyl-p-amino-phenyl stibinic acid; (3) stibamine and (4) stibhectine, and these, as well as the investigations previously referred to, indicate the great possibilities of improving the treatment of the various forms of leishmaniasis as well as of granuloma inguinale and other infections, by organic antimonyls and particularly trivalent compounds.

Absorption, Elimination and Toxicity of Tartar Emetic.—The absorption, elimination and pharmacological action of tartar emetic is quite similar to arsenic. The former, however, is absorbed more slowly and the dissociated antimony ion is more irritating to the stomach, the nauseating and emetic effects being due to direct local irritation of the stomach by the metal with the production of hyperemia and swelling of the mucosa, rather than the result of central action as formerly believed. The acidity of the gastric juice may facilitate dissociation but this occurs almost as rapidly in the intestines, on the skin or in the subcutaneous tissues. As a general rule, vomiting removes the compound from the stomach before passage into the intestines can occur except when very large doses are given when the intestinal irritation resembles the changes produced in the stomach. The acute and chronic gastro-intestinal lesions of poisoning, therefore, bear a resemblance to

those produced by arsenic. Furthermore, tartar emetic cannot be injected subcutaneously or intramuscularly in adequate doses on account of its irritant effects and when administered intravenously, due care must be exercised against perivascular extravasations, as in the administration of arsphenamin and neoarsphenamin. The nausea and vomiting of tartar emetic are due to its local irritant effects upon the gastric mucosa; likewise the colic and diarrhea, which are due to irritation of the intestinal mucosa. The increase of saliva and perspiration are secondary to nausea although a part of the increased activity of the salivary and other glands may be due to stimulation of these by elimination of the compound. When tartar emetic is given intravenously the elimination is largely by way of the urine, bile and gastro-intestinal mucosa as is true of the elimination of arsenic; with sufficiently large doses, the effects of gastro-intestinal irritation like nausea, griping, diarrhea and vomiting, may be produced. In just what form tartar emetic is eliminated, I am unable to state. Christopherson[4] is apparently of the opinion that the drug circulates and is eliminated unchanged, but I doubt that this is the case and surmise that dissociation occurs with the possible production of loose combinations of the metal with the plasma proteins.

Curiously the toxicity of tartar emetic by ingestion is higher than by intravenous injection, but this is largely because a portion of the drug is eliminated by the kidneys after intravenous administration with consequently less elimination of the gastro-intestinal tract and less irritation than when the drug is administered by swallowing.

Tartar emetic injected intravenously or administered by ingestion may produce the same cardiovascular effects as arsenic, since antimony acts upon the musculature of the heart and capillaries in the same manner producing depression of the heart and dilatation of the capillaries with a fall in blood-pressure; for this reason due care must be exercised in the administration of this compound to individuals with cardiac disease.

Tartar emetic, however, does not hemolyze or agglutinate erythrocytes either *in vitro* or *in vivo* as may the arsenical compounds. In my experiments concentrations *in vitro* as high as 1:20 had no effect upon either washed or unwashed corpuscles and the intravenous injection of 0.020 gm. per kilogram apparently produced no intravascular agglutination.

Tartar emetic administered by ingestion and intravenous injection either in the form of single large toxic doses or in small, repeated doses produces changes in the kidneys and liver quite similar to those produced by arsphenamin, neoarsphenamin and pentavalent compounds of arsenic. The vascular changes, however, are not as extreme; for example, in my experiments with tartar emetic administered to rabbits, I did not observe the typical large red kidneys produced by some of the inorganic and pentavalent compounds of arsenic. But the same kind and degree of epithelial degenerations in the kidney and liver have been observed sometimes amounting to fatty degeneration. The lungs show marked hyperemia and edema, but not the masses of agglutinated corpuscles produced by the arsenicals, nor have I noted the same changes in the meninges and suprarenal glands produced by arsphenamin. Brahmachari states that after the administration of a toxic dose of an antimonyl tartrate, the pathological changes are most marked in the lungs, kidneys, liver, pituitary and suprarenal glands, consisting chiefly of hemorrhages into the substance of these organs and destruction of their cellular elements. Similar changes were produced by toxic doses of the new aromatic organic antimonyls referred to above.

Antimony influences nutrition in somewhat the same manner as arsenic, but it is not employed for "tonic" effects as are compounds of the latter. Levy[5] states that the non-protein nitrogen of the blood may be increased in some cases given intravenous injections and very small quantities given repeatedly by ingestion are said to increase the glycogen and fat of the liver without apparently altering the nitrogen of the urine.

The maximum tolerated dose of tartar emetic for rats, rabbits and guinea-pigs by the slow intravenous injection of 1-per cent. solution is about 0.015 gm. per kilogram of weight. For a man weighing 70 kilograms or about 145 pounds this corresponds to 1.05 grams. The dose ordinarily given human beings by intravenous injection at one time is 5 to 10 c.c. of a 1-per cent. solution or 0.05 to 0.1 gm., so that these amounts are well within the range of safety, being 10 to 20 times under the maximum tolerated dose, and may be safely repeated. Doubtless some human beings are more susceptible than the average since fatal poisoning has followed the ingestion of amounts as small as 0.1 gm. (2 grains), so that it is never wise to give more than 1 or 2 c.c. of a 1-per cent. solution intravenously for the first dose, although the average dose is 5 to 10 c.c.

Ordinarily doses of these sizes produce no ill effects except occasionally a slight chill followed by rheumatoid pains in the joints associated with stiffness, especially involving the shoulders and usually noticeable in the mornings. Sometimes a slight metallic taste, slight nausea, giddiness, tachycardia, cough and tightness of the chest may be complained of as intolerance develops. When coughing, vomiting, colic, diarrhea and great debility occur, it is never safe to increase the dose but advisable to interrupt treatment until elimination has occurred. To the best of my knowledge acute toxic reactions of the arsenical

"nitritoid crisis" type do not occur, doubtless because the vasculotoxic effects are much less than produced by arsenic; intravascular agglutination does not occur at all and individuals are much less likely to have natural or acquired hypersensitiveness to antimony. The blood-pressure may be greatly reduced and tachycardia prove distressing. Lasky and Coleman[6] have reported ten deaths attributed to potassium antimony tartrate employed in the treatment of bilharziasis.

Randall[7] states that sodium antimony thioglycollate, which he has used successfully in the treatment of granuloma inguinale as a substitute for tartar emetic, is less toxic than the latter and ordinarily produces no symptoms at all in the usual dose of 5 to 10 c.c. of 1-per cent. solution by intravenous injection. Antimony thioglycollamide in dose of 0.08 gm. dissolved in 20 c.c. of sterile water and injected intramuscularly or intravenously every second day until as many as 15 to 20 injections have been given, is now preferred to the former salt.

Dosage and Administration of Antimony Compounds.—For the treatment of protozoan and metazoan diseases, intravenous injections are usually given because the dose by stomach must be so small in order to avoid nausea and vomiting due to local gastric irritation.

For intravenous injection tartar emetic, sodium antimonyl tartrate, sodium antimony thioglycollate, the triamid of antimony thioglycollic acid or urea-antimonyl tartrate may be employed in the form of 1-per cent. solutions in sterile distilled water or saline solution. The solutions are not bactericidal and must be sterilized by heating to 80°–100°C. for at least one half hour and preferably on each of two or three days in succession. Autoclaving is not permissible because dissociation may occur with a dangerous increase in toxicity. Solutions may be sterilized by filtration and this is the method commonly employed; I have also observed that if solutions are prepared with 0.3-per cent. phenol in water or saline and placed in a refrigerator for a day or two that chemical sterilization occurs without either heating or filtration.

The dose of tartar emetic is ordinarily 4 to 10 c.c. (0.04 to 0.1 gm.); according to Manson the largest tolerated dose is about 0.130 gm. (2 grains) equivalent to 13 c.c. of the 1-per cent. solution. Rogers advises about 2 c.c. or 0.02 gm. for each 10 pounds of weight and Faber and Schussler state that they have given a child of 27½ pounds as much as 0.1 gm. at one time, but these doses appear to be too large for most individuals and in my opinion the first dose should not be more than 2 c.c. since the tolerance of the patient is unknown. Commercial laboratories have prepared 1- or 2-per cent. sterile solutions in ampules ready for administration. The injections may be given by means of a syringe, as described in Chapter LIX, care being taken against accidental injection of the perivascular tissues. Doses of 5 c.c. may be given daily or at the rate of two or three per week without ill effects; as much as 30 to 40 injections, totally almost 2 grams of tartar emetic, having been injected without apparent untoward results.

Subcutaneous and intramuscular injections of tartar emetic cannot be given on account of the necrosing effects; I have tried small doses like 0.05 gm. in almond oil by intramuscular injection but the pain and disability is usually greater than follows injections of mercury. Martindale has employed injections of antimony oxid in dose of 150th grain in equal parts of glycerin and water; solutions of tartar emetic in phenolized water in dose of 0.5–1 c.c. carrying ½–1 grain (0.03–0.06 gm.) have likewise been employed. Randall states that antimony thioglycollamid may be administered by intramuscular or intravenous (preferred) injection every second day for as many as 15 to 25 injections, in dose of 0.08 gm. (about 1 grain) dissolved in 20 c.c. of sterile water.

The dose of tartar emetic by mouth is ordinarily about 0.005 to 0.008 gm. or 1/12th to 1/10th grain; larger doses are apt to produce nausea and emesis.

Oral administration is sometimes advised following a series of intravenous injections and Castellani and Chambers have employed the following formula:

Antimonii et potassii tartrati	gr. v (0.3 gm.)
Sodii bicarb.	gr. xxx (1.8 gm.)
Glycerini	
Aq. chloroformi	aa f℥i (30 c.c.)
Aq. distil.	q.s. ad f℥ iii (100 c.c.)

The dose is one to two teaspoonfuls in water three times a day.

Mechanism of Parasiticidal Activity of Antimony Compounds.—The mechanism of curative activity of tartar emetic in such protozoan diseases as the various forms of leishmaniasis and in such metazoan diseases as schistomiasis is as yet unknown. As discussed in Chapter XIII, Voegtlin and Smith are of the opinion that the pentavalent organic compounds are first reduced to a trivalent state before trypanocidal activity is produced. It is highly probable that all compounds become dissociated and that the antimony ions constitute the parasiticidal agents. Whether processes of oxidation occur with the production of new compounds analogous to the trivalent oxids of the organic arsenicals or whether union with the plasma proteins occurs with the formation of antimony-albuminates; cannot be stated. It is likely that the mechanism is similar to that shown by mercury in its spirocheticidal activity and that antimony ions directly attack the protoplasm of those parasites for which it has an affinity. Why antimony poisons the protoplasm of some protozoa and metazoa and not others cannot be stated, just as we are unable to explain the higher spirocheticidal effects of mercury for *Sp. pallida* of syphilis than for *Sp. pertenuis* of frambesia tropica (yaws).

Doubtless the readiness with which antimony compounds dissociate into antimony ions influences both parasitropic and organotropic effects. As in the case of mercurials I surmise that it is possible to classify the organic and inorganic compounds into the same classes of full complex, pseudo-complex and half complex compounds and that the most rapidly dissociated compounds will prove the most toxic for both the body cells and the parasites.

Since intravenous injections of tartar emetic may produce a slight leukocytosis, at least in rabbits, it is possible that the specific parasiticidal effects are enhanced or aided by certain non-specific agencies commonly designated as the non-specific protein reactions so commonly observed following the intravenous injection of vaccines and other protein substances as well as some of the metals in colloidal suspension. Whether or not tartar emetic stimulates antibody production, cannot be stated, since immunological investigations of this kind do not appear to have been made. As stated in Chapter XIII, I have observed a temporary resistance of about five days duration in rats to infection with *T. equiperdum* after the animals had been sterilized of a previous infection by tartar emetic. This resistance, however, may have been due to retained medicament and I very much doubt that the antimonyls stimulate immunological resistance and believe that the specific curative effects of these compounds are due to the action of ionic antimony aided possibly, by certain non-specific agencies in the way of leukocytosis and bone marrow stimulation; in short, that the mechanism is analogous to that described in Chapter XIV for mercury.

Chemistry, Pharmacology and Toxicology of Ipecac and Emetin, in Relation to the Chemotherapy of Protozoal and Metazoal Diseases.—The curative activity of ipecac and especially of emetin hydrochlorid in amebic dysentery has been well established and the latter especially has proven useful in the treatment of various other protozoan and metazoan diseases, particularly in

the various types of schistosomiases or bilharziases; indeed in the treatment of some of these diseases emetin is our main drug and for this reason is deserving of particular interest and study not only because of the practical results in treatment but likewise in relation to the possibility of improving the chemotherapy of these diseases.

Chemistry of Ipecac and Its Alkaloids, in Relation to the Chemotherapy of Protozoan and Metazoan Diseases.—While various preparations of ipecac root itself have undoubtedly proved amebacidal *in vitro* and curative for the amebic dysenteries, one of its alkaloids, emetin, has proved more efficacious and more useful. Harris, in 1819, claimed that ipecac more or less freed from its alkaloids ("de-emetinized") was equally effective and less disagreeable, but Vedder[8] and others have since proved that while they may be less disagreeable, they are apt to be therapeutically inert.

In other words the parasiticidal effects of ipecac are due almost entirely to its two most important alkaloids namely, emetin and cephaelin; psychotrin is much inferior. But both of these and particularly cephaelin, are capable of producing nausea and vomiting by local irritation of the stomach when swallowed and by central stimulation when injected and it would be a great triumph for chemistry to synthesize a new compound of equal parasiticidal activity but of lesser toxicity and especially for the gastro-intestinal tract and vomiting center. As a matter of fact, but little has been done in this promising and important field. It is true that various salts of emetin have been prepared but they are about equal in toxicity and for all practical purposes, the hydrochlorid is best for treatment. Furthermore, some emetin derivatives with higher alkyl esters have apparently proven more parasiticidal than emetin, at least for amebas *in vitro*, but so far no substitute has been offered for emetin.

Enough work has been done to show that emetin is the best constituent of ipecac for the treatment of amebic and other protozoal infections; nothing is apparently to be gained in the way of further efforts toward the isolation of other alkaloids or glucosides from the root, but it is possible that systematized chemotherapeutic investigations may result in the elaboration of new compounds of superior qualities and especially for encysted protozoa. Quinin, *chaparro amargosa* and other vegetable substances, as well as antimony and other metals, are also amebacidal, but the chemotherapy of the amebic infections as well as other protozoal and metazoal diseases is still in an unsatisfactory state. It is particularly desirable to discover compounds of greater parasiticidal activity and especially those of greater penetrability, in order to reach and destroy parasites and their ova enmeshed in the deeper tissues and especially those capable of encystment in the course of their life cycles.

Pharmacology and Toxicology of Ipecac and Emetin, in Relation to Methods of Administration.—Ipecac itself can be only administered by ingestion or rectal injection and since Rogers[9] in 1912, encouraged by Vedder's investigations, showed the superiority of emetin hydrochlorid by subcutaneous injection in the treatment of amebic dysentery, this alkaloid has almost supplanted preparations of the root. As shown by Eggleston and Hatcher[10] and others, cephaelin is more irritant and about twice as toxic and emetic as emetin; psychotrin is less toxic but likewise less parasiticidal, and ipecacuanhic acid, ipecacuanhin and various cephaelin esters have been found more or less inert, so that for all practical purposes, emetin is preferred and especially when subcutaneous injections are to be given.

Ipecac and emetin are quite irritant for the stomach and largely produce nausea and vomiting by local irritation, being analogous to tartar emetic in this respect, rather than by action upon the medullary center, since the dose of emetin by subcutaneous injection necessary to cause vomiting is larger than the emetic dose by ingestion. In order to overcome these nauseating and emetic effects, the drugs have been administered in various ways to get them through the stomach without irritation, as in the form of salol-coated pills or difficultly soluble preparations like emetin-fuller's earth adsorbate and emetin-bismuth iodid; also by rectal infusion, which, however, is of limited value since only a small part of the large intestine is reached unless the enema is given with special skill and methods.

For the treatment of amebic dysentery, however, these methods may be sufficient for bringing the drugs in contact with the parasites in the intestinal mucosa, but since absorption from the gastro-intestinal tract is slight, not enough emetin is likely to be absorbed for the treatment of urinary and pulmonary schistosomiasis or bilharziasis and other blood and tissue infestations with the parasitic trematodes. For the treatment of these diseases and other infestations of the blood and various internal organs by the parasitic trematodes, subcutaneous injections of emetin are very much to be preferred to oral administration.

Curiously, emetin injected subcutaneously is apparently much less irritating than when applied to the skin or mucous membranes. The nausea, vomiting and diarrhea are largely

due to irritation of the gastro-intestinal mucosa sometimes amounting to marked and severe inflammatory changes and hemorrhages; in the eye it may produce severe conjunctivitis, but the gums and buccal mucosa are more resistant permitting the local application of 0.5- to 1-per cent. solutions for the treatment of gingival amabiasis. Rectal and vaginal douches, however, may produce considerable irritation.

Strangely enough very little is known of the elimination of emetin and especially after subcutaneous injection. Lowin,[11] who has studied this subject with particular care, states that he could find no traces in either the urine or gastro-intestinal contents and Lyons[12] also failed to find it in the feces. But I feel that some of the drug must be eliminated in the urine since the kidneys may show acute hyperemia, hemorrhages and even epithelial degenerations in poisoning; furthermore, it would appear that elimination by this route affords an explanation for the curative effects of the drug in urinary bilharziasis due to the presence of *Schistosoma hæmatobium* and its eggs in the veins and tissues of the urinary bladder. Surely the gastro-enteritis is due in part to the elimination of the drug by the intestinal mucosa, for how else may we explain the curative effects of emetin in amebic dysentery and intestinal bilharziasis (caused by the worms and eggs of *Schistosoma mansoni*)? Furthermore, it would appear that a part of the drug may be eliminated in the bile, accounting for the parasiticidal effects in the intestinal canal and likewise for its curative action in hepatic bilharziasis or "Katayama disease," caused by the worms and ova of *Schistosoma japonicum*, as well as possibly, in liver infestations by *Fasciola hepatica* and *Fasciola gigantica*. On the other hand, however, it is well established that emetin injected subcutaneously or intravenously has no effect or almost no effect upon *Amœba coli* in the intestinal tract of man. This species is non-pathogenic, but experimental studies have shown that it is readily destroyed by ipecac and emetin *in vitro* and it is difficult to understand why these drugs have little or no influence upon it *in vivo*, even when the compounds are administered by mouth. Apparently emetin can only reach those amebas in the deeper tissues of the intestinal walls, but failure to remove those *Amœbae coli* and *Endamœbae histolytica* on the mucosa indicates that when ipecac and emetin are administered by stomach, absorption probably occurs in the upper portion of the small intestine leaving little or none in the intestinal contents reaching the colon unless large doses are given; also that if these drugs are eliminated at all in the ileum and colon, it must be only in traces too small under ordinary circumstances to appreciably influence the free living amebas and still less the encysted parasites.

Furthermore, it would appear that emetin injected subcutaneously is only very slowly eliminated; Udonda and Carulla, Savignac and Alivisatos and others have recorded instances of polyneuritis and urticaria due to a cumulative action of emetin in which it appears that the drug was retained for periods ranging from three months to more than a year. I shall refer shortly to this subject again as it bears an important influence upon the toxicity and administration of emetin.

The toxicity of emetin for the lower animals by subcutaneous and intravenous injection has been shown by Levy and Rountree[13] to vary greatly with different preparations of the alkaloid and when intravenous injections are given, the dilution of the drug, rate of injection and susceptibility of the animal employed, exert important influences. Vedder observed that 0.0025 gm. per kilogram was about the lethal dose for rabbits by intravenous injection; Levy and Rountree observed that from 0.004 to 0.018 gm. per kilogram was the lethal dose for dogs and cats, while Smith and I[14] found that by this route of administration, 0.016 gm. per kilogram was immediately lethal for rats and 0.010 to 0.0129 gm. per kilogram immediately lethal for rabbits. By subcutaneous injection Levy and Rowntree found that the lethal dose for dogs and cats varied from 0.003 to 0.029 gm. per kilogram according to the preparation used but as a general rule doses of 0.003 to 0.005 gm. per kilogram killed in from two to five days. If the average *maximum tolerated dose* by subcutaneous injection is taken as about 0.003 gm. per kilogram, corresponding to 0.210 gm. per 70 kilograms or 145 pounds, it is apparent that the usual adult dose of ½ grain (0.03 gm.) is well within the margin of safety, although repeated doses of this size have produced severe reactions and not a few deaths, especially in hyper-susceptible individuals.

Emetin injected subcutaneously or intravenously may cause a marked fall in blood-pressure mainly due, according to Levy and Rountree, to a direct toxic action on the heart with acute dilatation and death in diastole; vasomotor paralysis may also occur. Smaller doses produce cardiac irregularity due to fibrillation of the ventricles and the coagulation time of the blood is delayed. I have found no evidences of agglutination of erythrocytes in dilutions as low as 1:10 and, while washed corpuscles may undergo slight hemolysis at this concentration, whole blood is not hemolysed because of the protection afforded by the plasma. Chopra[15] has shown that in rabbits, marked histological changes may occur in the heart consisting of cloudy swelling, atrophy and fibrosis of the muscle cells. Emetin is also toxic for the capillary endothelium, producing marked degrees of petechial hemorrhage. After toxic doses, the kidneys may show a hemorrhagic type of nephritis with albuminuria; the liver usually shows acute hyperemia and cloudy swelling while the entire

gastro-intestinal tract from "cardia to anus" presents a severe hyperemia with hemorrhages and epithelial degenerations.

Emetin, therefore, is a drug requiring considerable care in administration and especially when repeated doses are required as is usually the case. Levy and Rountree have collected a large number of case reports of very severe reactions and several deaths; Lyons[16] has also recorded a number of toxic reactions and states that emetin should not be administered by mouth at all since even ½ grain doses may produce nausea, vomiting, griping and diarrhea.

Baermann and Heinemann[17] have noted distressing and even alarming symptoms following doses much larger than are usually employed. I believe that doses of ⅓ to ½ grain by subcutaneous injection are as large as demanded and that larger doses, especially when repeatedly given, are dangerous and uncalled for; intravenous injections are not usually indicated or required and should not exceed ¼ grain (0.015 gm.) for an adult of average weight. As stated by Lyons, the subcutaneous injection of ⅓ grain causes but little discomfort, but 1 grain doses may produce a severe inflammatory reaction lasting for one to two weeks. Since these reactions probably delay absorption, he advises small and repeated doses as being preferable to single large ones.

In human beings emetin may produce, therefore, a train of toxic symptoms consisting principally of such gastro-intestinal effects as nausea, vomiting, abdominal pain and diarrhea; such cardiovascular effects as arrythmia, fall in blood-pressure, petechial hemorrhages (including purpuric skin rashes), cerebral and pulmonary edema and such general effects as peripheral neuritis, extreme malaise and muscular debility. Polyneuritis is especially prominent. Some individuals are apparently hypersusceptible to the effects of ipecac and its alkaloids; skin tests have not been reported upon in these, but I surmise that they may be elicited just as in quinin allergy. At least it is always well to make the first dose of emetin very small (⅛ grain) in order to test the susceptibility of the patient before larger doses are given.

Mechanism of Parasiticidal Activity of Emetin.—Emetin and cephaelin are known to be very powerful amebacides and protoplasmic poisons in general *in vitro* for many protozoa and metazoa.

Experiments *in vitro* with cultures of ameba, with *Ameba histolytica* in dysenteric stools and with *Endameba gingivalis* in the pus of pyorrhea (Rigg's disease) have shown that dilutions of emetin 1:10,000 and even as high as 1:100,000 may destroy the parasites, with loss of motility, swelling and granular degeneration of the protoplasm. In other words, emetin apparently unites directly with the protoplasm of amebas and other parasites, including some of the bacteria and notably the anthrax bacillus, bringing about certain morphological changes and death. It has an affinity for certain parasites just as quinin is a general protoplasmic poison and especially for malarial parasites. When adult human subjects are given 0.05 gm. (about 1 grain) by subcutaneous injection, the concentration in the blood probably reaches at least 1:80,000 and when several doses of this size are administered at close intervals, the concentration is probably even greater so that we may assume that emetin destroys amebas and other parasites in the tissues by direct attack. At least, there is no evidence of the production of new compounds in the tissues or of any influence upon increasing antibody production. In other words, the action appears to be a direct one just as quinin probably destroys the malarial parasites by direct toxicity. Dale and Dobell,[18] however, do not agree with this hypothesis. In their experiments with *E. histolytica* infestations of the colon of young kittens, they observed *in vitro* that these parasites would sometimes withstand the action of emetin at 1:1000 and even 1:100 for an hour; in no case was any appreciable effect produced by a 1:10,000 solution. On the basis of these observations they have abandoned the idea that the curative activity of emetin is due to more or less direct action on the ameba, but suggest that emetin may produce some obscure alteration of the tissues of the host, rendering them perhaps more resistant to the cytolytic action of the amebae.

Amebas and other parasites capable of encystment may resist the effects of emetin; apparently the drug is unable to penetrate the parasites just as quinin is ineffectual for the sexual types of malaria and especially of *Plasmodium falciparum*. Probably future chemotherapeutic researches will disclose a means of combining emetin with a dye or some other substance capable in greater degree of piercing these encysted or resistant forms; at least, there is urgent need for studies of this kind to improve the emetin treatment of amebic and other infestments and especially for the treatment of their relapsing and chronic diseases.

Dosage and Administration of Emetin.—Emetin hydrochlorid is generally administered by *subcutaneous injection* in the treatment of amebic dysentery and other protozoan and metazoan diseases. A great difference in opinion has been expressed in regards to dosage, probably because different observers have worked with preparations of emetin varying greatly in toxicity, as so well shown by the investigation of Levy and Rountree referred to above. It would appear, however, that the average dose for an adult is ⅓ to ½ grain (0.02 to 0.03 gm.) by daily injection not exceeding a total of 15 grains in any one series of injections on account of the danger of cumulative effects and especially the production of polyneuritis. If 1 grain is given at one time, it is my practice to divide this dose into two injections in order to avoid the severe local reaction that may follow depositing 1 grain in the tissues. I have observed, however, that different makes of emetin hydrochlorid have varied in this regard and some may be given in dose of 1 grain without any more local reaction than follows an injection of quinin and urea hydrochlorid. Intramuscular injections are said to be more painful. Dosage, however, depends upon individual cases, but as a general rule it is inadvisable to give more than 10 to 15 consecutive daily injections.

Intravenous injections are sometimes employed. The dose should not be over ¼ grain (0.015 gm.) dissolved in at least 10 to 20 c.c. of sterile saline solution or water and very *slowly* injected. Concentrated solutions have been given, but diluted solutions are to be preferred, just as in the administration of quinin. It is well to have in readiness a 1:1000 solution of adrenalin and to inject 0.5 c.c. intramuscularly if cardiac depression and vasomotor paralysis develops.

Oral administration may be given, but the dose should not be over ⅙ to ½ grain (0.01 to 0.03 gm.). Keratin or salol coated tablets should be used, in order to pass the drug through the stomach into the intestines and thereby reduce the chances of producing local irritation, nausea and vomiting.

Colonic irrigations have been employed as 0.1 gm. of emetin dissolved in 1000 c.c. of water or saline (1:10,000 solution). The practical value of colonic irrigations with solutions of emetin or ipecac has been questioned, however, since the vegetative amebas are easily destroyed by irrigations with quinin, salicylic acid, silver nitrate, etc., without the danger of producing the direct irritation of the colon by emetin or ipecac, constituting the so-called "intestinal intolerance" for these compounds.

Chemotherapy of Leishmaniasis.—Since the organic arsenicals and especially arsphenamin and neoarsphenamin have yielded such excellent and encouraging results in natural and experimental spirochetal and trypanosonial infections of man and the lower animals, it was expected that these compounds would prove effective in diseases caused by other flagellates. But such has not proven to be true. For example, belonging to the family of trypanosomes is the genus *Leishmania*, parasites bearing a strong resemblance to the trypanosomes, except that they have no undulating membrane at any stage of development and for which arsphenamin and neoarsphenamin are ineffective while antimony compounds are so highly destructive as to constitute a specific form of therapy. "Leishmaniasis," therefore, is a general name including several diseases caused by different species of the genus *Leishmania*, just as the term "spirochetosis" includes several diseases due to different species of spirochetes, and as the term "trypanosomiasis" includes a number of diseases caused by different species of trypanosomes.

The parasites live chiefly inside of endothelial cells, but may be found in leukocytes or within the cells of the internal organs, such as the liver, spleen, etc. In the intracellular stage the parasites appear as non-flagellated, small,

oval, cytoplasmic bodies provided with a trophonucleus and a kinetonucleus. Several species have been cultivated on blood agar *in vitro* in which they regain the flagella.

Leishmania have been found in man, horses, rabbits, and other mammals inside of the endothelial cells of the capillaries of the liver, spleen, bone marrow, lymphatic glands, intestinal mucosa, in the blood of the femoral, portal and hepatic veins and sometimes in the peripheral blood, especially just before death, either free or within leukocytes. Infection is known to take place by direct contact and may be transmitted through an intermediate host, as bed-bugs, mosquitoes and other insects.

Diseases Produced by Leishmania.—Just as many pathogenic species of trypanosomes, spirochetes and other flagellates are known to occur in man and the lower animals, so there are likewise several pathogenic species of *Leishmania*. Our knowledge of these, however, is still incomplete insofar as differentiating among the various kinds is concerned, although their morphology and life history has been carefully and extensively studied. Among the species known to produce disease are the following:

(1) *L. donovani*, which produces internal leishmaniasis or *tropical* (*Indian*) *kala-azar*. *L. donovani* var. *archibaldi* is a subvariety of the same parasite.

(2) *L. infantum*, which produces kala-azar of children designated as *Mediterranean kala-azar*. *Canine kala-azar* is probably caused by the same parasite.

(3) *L. tropica* (Wright), which causes a cutaneous infection variously known as "*oriental sore*," "*Bagdad sore*," "*Delhi sore*," "*Aleppo boil*," etc. This species probably includes a subvariety called *L. americana* or *brasiliensis*, producing "espundia," a mucocutaneous infection in South America, and a similar disease in India and neighboring countries, called "Indian oropharyngeal leishmaniasis." Probably *L. nilotica*, producing a non-ulcerating keloid-like lesion designated as "Leishman's nodules" is another subvariety of this parasite.

While the chief endemic centers of Leishmania diseases according to Laveran[19] are the Ganges basin and Madras in India, China between the Yang-tse river, Peking and the Yellow Sea, and the Mediterranean littoral, yet *L. tropica* infections are quite common in South America, especially involving most of the continent east of the Andes between Panama and latitude 35°S. Cases of both kala-azar and oriental sore have been reported in the United States by Wright[20] who first described and established the organism in oriental sore, MacEwen,[21] Spencer,[22] Smith,[23] Fox,[24] Talbot and Lyon,[25] Faber and Schussler,[26] and Lambert.[27] Indeed, cases of leishmaniasis and particularly of oriental sore may be much more frequent in this country than surmized and especially since the prolonged incubation period may readily enough permit individuals from the endemic areas arriving in this country without lesions to subsequently dvelop the disease. Furthermore, oriental sores may readily escape detection and from the standpoint of laboratory diagnosis, biopsies with the examination of sections of tissue for the organisms are to be preferred to smears and cultures.

Whether the type of ulcerating granuloma of the genital organs and groins of both sexes and especially prevalent among Negroes designated as *granuloma inguinale*, is another form of cutaneous leishmaniasis, is not definitely settled. This disease has been known for many years, but has been confused with the venereal ulcers caused by *Sp. pallida*, *B. ducrey* and unidentified types. In 1904, Donovan[28] described certain inclusions in the mononuclear cells found in the lesions which have since become widely known as the "Donovan bodies" and generally regarded as the cause of the infection. Donovan regarded these organisms as protozoa; Flu[29] believes that they are chlamydozoa and might belong to the capsulated bacilli, while Carter[30] regards them as a gregarine type of crithidia or herpetomonads. Aragao and Vianna[31] also regard them as bacteria, but belonging to a new type, designated as "kalymmato granulomatis;" Walker,[32] Randall, Small and Belk[33] and Small and Julianelli[34] regard the organism as a bacterium of the *Bacillus mucosus* group. Certainly the spirochetes described by Wise,[35] Maitland[36] and MacLennon[37] are not to be regarded as the etiological agent and while the exact nature of the inclusion bodies is unknown, I believe that they are probably protozoa belonging to the genus *Leishmania;* this opinion, however, is largely based upon the remarkable curative properties of tartar emetic for the infection which exerts a similar effect in kala-azar, oriental sore and other forms of leishmaniasis. At least I believe it may be stated that, if *granuloma inguinale* is a bacterial infection, treatment with tartar emetic constitutes the most successful form of chemotherapy in a bacterial disease known to-day, and since similar bodies have been

found in the various cutaneous and mucocutaneous lesions of other *Leishmania* infections, I believe that it is highly probable that *granuloma inguinale* is of similar origin. In this connection I may state that Johns has recently failed to cultivate the Donovan bodies and is inclined to believe that they are not of bacterial nature.

Why there should be such a diversity of lesions and diseases due to such closely related varieties of *Leishmania* cannot be stated, just as we are unable to explain why frambesia tropica or yaws is almost entirely a cutaneous or mucocutaneous disease caused by a spirochete so closely similar to *Sp. pallida* that only cross-immunity or protection tests serve for differentiation. Indeed, the number of varieties and subvarieties of *Leishmania* appears to be constantly increasing, but it is highly probable that future investigations will show that while a number of clinical lesions or diseases may be produced, the number or varieties of *Leishmania* is not as great as surmised; for example, it is stated that monkeys inoculated with *L. tropica* are protected partially or completely against *L. donovani*, which shows the very close relationship between the parasites of these two well-defined diseases. On the other hand, Brahmachari[38] has recently described a cutaneous form of kala-azar (*L. donovani*) occurring in persons incompletely cured, which does not resemble oriental sore in any respect, and it is stated that some cases of oriental sore and espundia may have systemic lesions and symptoms which are not like those of kala-azar. Faber and Schussler have also mentioned that at least one case has been known to have become infected at different times by *L. donovani* of kala-azar and *L. tropica* of oriental sore, indicating that the parasites were not closely related; but as stated above, monkey cross-inoculation tests have shown that cross-immunization may occur and it is likely that, in the case referred to, the immunity conferred by the first infection disappeared or that superinfection is possible in leishmaniasis, just as it appears to be in some cases of syphilis.

Pathology and Immunity of Leishmania in Relation to Chemotherapy.—All varieties of *Leishmania* exhibit the same propensity for growing inside of cells and especially the endothelial cells of the vascular and lymphatic organs. In tropical kala-azar the vascular and lymphatic spaces of the liver, spleen, bone marrow and lymphatic glands are principally involved although the pancreas, kidneys, suprarenals, testicles, lungs and other organs may be similarly affected. In infantile kala-azar the spleen and liver are especially involved, although the lesions may be so similar to those in tropical or Indian kala-azar that this special clinical type may constitute nothing more than an infantile or juvenile variety of the disease. The parasites are apparently deposited in the capillaries and lymphatics by trauma and direct contact or by the bites of infected insects; apparently the disease is not congenitally transmissible, although when the testicles are involved the possibility of infection of the female exists with either paternal or maternal infection of the ovum or fetus. The parasites may remain at the site of inoculation and produce nothing more than a local sore or lesion with involvement of the neighboring lymphatics, as in oriental sore and granuloma inguinale. Or they may be carried to the internal organs and especially the spleen and liver, where endothelial cells are invaded; as these rupture, the parasites are discharged into the blood and carried to other organs. Toxins are apparently produced responsible in part for the cloudy swelling, fatty degeneration and even necrosis of the parts infected, as in the intestinal and other mucous membranes and the skin, although these changes may be due in part to the cutting off of the blood supply by the swollen endothelial cells of the capillaries; as would be expected fibrosis is produced in the chronic lesions. I have briefly reviewed this subject of the pathological changes to

indicate that, in the treatment of the disease, a drug like tartar emetic gaining access to the blood and lymph must penetrate the endothelial cells to reach the parasites and that this action may be still further hindered by fibrous tissue encapsulations; in other words, that treatment must be prolonged and that rapid sterilization is not to be expected except in the more recent and acute infections.

As is true of other protozoan infections like trypanosomiasis, syphilis and malaria, immunological resistance is not highly developed and the natural cure of man infected with *L. donovani* and *L. infantum* at least, is quite rare. It would appear, however, that one attack of oriental sore confers an immunity against the disease and it is stated that the Bagdad Jews have inoculated their children in the legs, in order that disfiguring lesions on the face, resulting from infection acquired in the usual way, might be prevented.

Cases of oriental sore and granuloma inguinale may recover frequently without medicinal aid, but only very slowly and usually with considerable tissue destruction. Some immunological resistance, however, may be acquired in all varieties of leishmaniasis responsible for holding the infection in check, but as a general rule this is gradually exhausted or overcome with progression of the disease. I mention these factors to show that medicinal treatment is required for recovery and that antimony apparently kills the *Leishmania* by direct toxic effect rather than indirectly by stimulating the production of antibodies or other specific immunological agencies.

Specific and General Treatment of Internal Leishmaniasis; (Tropical or Indian Kala-azar and Mediterranean or Infantile Kala-azar).—Tartar emetic (antimony and potassium tartrate) acts as a specific in the treatment of this disease; other antimonyls like sodium antimonyl tartrate and various colloidal antimonyls have also yielded excellent results as would be expected since the dissociated antimony ion appears to be the curative agent. Naturally a large number of other agents have been tried and Noguchi[39] has recently described an extensive series of experiments *in vitro* and *in vivo* with numerous antimony, bismuth, arsenical and dye compounds. According to Jemma[40] who has published an excellent historical review of the use of antimonyls in the treatment of leishmaniasis, tartar emetic was first employed by Caronia and Di Cristina. Brahmachari[41] prefers urea-antimonyl tartrate by intravenous and intramuscular injection in the same or slightly larger dose than tartar emetic and states that, while the therapeutic results are just as good, the untoward or distressing after-effects are much less, although in his opinion the best antimonyl for the treatment of kala-azar has not yet been discovered.

As a general rule, the drugs are administered by intravenous injection in the form of sterile 1-per cent. solutions. The average dose for adults is 5 to 10 c.c.; children from one to five years may receive 1 to2 c.c. and from five to twelve years from 3 to 5 c.c. Smyly[42] has recently stated that in experimental infections in rabbits only intravenous injections are of value; intramuscular and intraperitoneal injections were found much less efficacious.

The injections are generally given daily for 5 to 10 doses; then every other day for about 10 more doses and finally once or twice a week until a cure is effected. Intramuscular injections may be substituted, although these are apt to prove quite painful. Oral administrations may supplant these injections if the drug is well borne and are especially useful as a form of "follow up" treatment after a series of intravenous injections. Indeed, after the disappearance of lesions it would appear advisable to give a short series of 3 or 4 intravenous injections at intervals of a week twice a year for two or three years to insure against relapses in case complete sterilization has not

been secured or is impossible because of the chronicity of the lesions or drug intolerance. Atoxyl, arsphenamin and other arsenicals, as well as quinin, methylene-blue and other compounds have been employed but without success.

The heart must be carefully watched when intravenous injections of the antimonyls are being given, intramuscular injections of 1:1000 adrenalin in dose of 0.5 to 1 c.c. being especially useful for counteracting the vasodilating effects and drop in blood-pressure. Hemorrhagic lesions may be combated by the oral administration of calcium lactate in dose of 10 grains three times a day or by intravenous injections of 5–10 c.c. of 10-per cent. solutions of calcium chlorid. Arsphenamin and its substitutes apparently do not exert any marked specific effects upon *Leishmania*, but may be of service for correcting the anema usually associated with both the tropical and infantile types of kala-azar.

Specific and Local Treatment of External Leishmaniasis (Oriental Sore, Espundia and Indian Oropharyngeal Leishmaniasis).—Tartar emetic and other antimonyls are likewise regarded as specifics for the treatment of this type of leishmaniasis. As a general rule, intravenous injections of a sterile 1-per cent. solution are given in dose of 5 to 10 c.c. every day for five to ten days followed by ten to twenty additional injections every other day and finally once a week until a total of fifteen to thirty injections have been given. Intramuscular injections may be substituted and especially in young children, but are apt to prove quite painful. Oral administration may be given as a "follow up" form of treatment.

Excision of the lesions has been advised when they are so located that a rather wide excision can be made to remove infected capillaries and lymphatics, without too much deformity or tissue loss. This would appear to be an excellent practice, being similar to the excision of the malignant pustule or local anthrax lesion. After excision it is advisable to apply a 1-per cent. solution of tartar emetic for the local destruction of the parasites, but the powder itself produces too much pain. Various other local applications have been advised as potassium permanganate, methylene-blue, silver nitrate and other silver preparations, etc. Even though excision is done, it would appear advisable to follow with intravenous injections of tartar emetic to destroy parasites escaping surgical removal and especially those in the neighboring lymphatics; recurrences have sometimes occurred at the margins of the wound following excision when parasites remained in the tissues.

Oriental sores tend to heal spontaneously, but the course of the infection is so prolonged that specific treatment is always advisable not only to shorten the duration of the disease but as a safeguard against autoinoculation and transmission to others. Various local applications like 2- to 15-per cent. tartar emetic in lanolin may aid, but this particular preparation tends to produce irritation with the production of pustules, and intravenous injections of tartar emetic or some other antimonyl appears to be the best treatment. Scott[43] reports that injections twice or three times a week starting with 0.06 gm. (6 c.c. of 1 per cent. solution) and increasing by 1 or 2 c.c. gives best results and that in early cases before ulcer formation, complete cures are to be obtained in ten to fourteen days. Castellani[44] has recently stated that good results have followed local applications of ordinary phosphorus oil (B.P.) together with the injection of 3 to 5 minims under the skin around the nodule or into the lesion itself. *X*-ray treatment, freezing the lesions with carbon dioxid, etc., have also yielded good results in the hands of Adams and others.

Antimony Fastness of Leishmania in Relation to Treatment.—As stated in Chapter XIII, it is well known that various pathogenic trypanosomes may

be rendered antimony-resistant and it would appear that the same possibility exists in relation to the treatment of kala-azar and cutaneous leishmaniasis. According to Nasso and Mallardi[45] the doses of tartar emetic have to be increased to 0.05 or 0.07 gm. with longer intervals between injections, when this condition is developed. When resistance to tartar emetic is combined with acquired intolerance, they advise an arrest of treatment for several weeks to be followed by a series of small doses every two or three days and state that no child needs to die from leishmaniasis, if the administrations of tartar emetic are carefully and skilfully given.

Criteria of Cure of Leishmaniasis.—In the kala-azars it is advised by Struthers,[46] Muir[47] and others that specific treatment be continued until there are (1) an increase in weight and general well-being with a healthy state; (2) a normal temperature for at least six to eight weeks; (3) a reduction in the size of the spleen and (4) an increase in the leukocytes and hemoglobin. Rogers[48] lays great stress upon the leukocyte-erythrocyte ratio and when this is 1:1,500 or less, active kala-azar is almost certainly present. When conditions permit, at least one splenic puncture may be advisable for the detection of parasites before treatment is stopped and it may be that Napier's[49] gel-test is of value as a criterion of cure when it is gradually reduced from a positive to a permanently negatively reacting state.

Specific Treatment of Granuloma Inguinale and Other Granulating Ulcers.—The use of tartar emetic in the treatment of these ulcerating granulomata is credited to Aragao and Vianna[50] and since then numerous reports by Randall, Small and Belk,[51] Low and Newham,[52] Cummings,[53] Hoffman,[54] Reed and Wolf,[55] Cuthbert,[56] Lynch,[57] Schochet,[58] Johns[59] and others indicate that intravenous injections of tartar emetic frequently, and indeed usually, brings about a rapid cure of granuloma inguinale showing the presence of Donovan's bodies in smears of the lesions or in sections of excised tissue. Furthermore, as shown by the reports of Lynch and of Pereira,[60] this drug has effected the cure of other granulomata and granulating ulcers as cachar sores and leg ulcers in which these bodies have not been found, indicating that the antimonyls may have a parasiticidal effect in a variety of infections of this class. Syphilitic ulcers, of course, are not benefited by antimony and rapidly heal under treatment with arsphenamin and its substitutes. Chancroids may be benefited to some extent by injections of tartar emetic associated with appropriate local measures, but best results with the antimonyls have been secured in granuloma inguinale showing Donovan's bodies in the mononuclear cells. Local treatment for this infection has generally failed, although complete excision of the ulcers has been occasionally successful.

Sterile 1-per cent. solutions of tartar emetic in water or saline have been generally employed by intravenous injections. The first dose may be 2 c.c. followed at daily intervals by 4 to 10 more injections in dose of 5 to 10 c.c. each according to the tolerance of the patient for the drug. In some cases this treatment is sufficient, but extensive and long standing cases will require a longer series of injections at the rate of 2 or 3 per week and finally one per week, until as many as 15 to 30 injections have been given. Even after healing is complete, it may be well to give an additional series of 3 or 4 injections at weekly intervals to insure a complete and permanent cure, if the patient bears well with the drug and if there are no signs of renal irritation. Dosage should be carefully arranged and controlled for each individual case, including a careful examination of the urine for albumin, casts and erythrocytes at least once a week. As previously stated Randall[61] has also employed intravenous injections of antimony thioglycollamide in dose of 0.08 gm. dissolved

in 20 c.c. of sterile distilled water. As many as 15 to 25 injections are given at two day intervals and he recommends that at least 12 injections be given after the first healing has taken place to insure permanent cure.

Chemotherapy of Amebic Dysentery and Other Amebic Infestments.—While a host of pathogenic endamebas have been described varying from one another morphologically in greater or lesser degree, probably only four need command our attention from the standpoint of chemotherapy, namely, (*a*) *Endamœba histolytica* and (*b*) *Endamœba tetragena*, producing the dysenteries, liver absesses and other complications; (*c*) *Paramœba hominis* (Craig) and (*d*) *Endamœba gingivalis* (Gros) sometimes associated with Rigg's disease (pyorrhæa gingivalis). *Amœba coli*, probably the best known of all, is now generally considered a saphrophyte and incapable of producing dysentery and associated lesions. In the United States many physicians, indeed, probably the majority, have paid scant attention to amebic dysentery, because they have regarded it as an extreme rarity. Nevertheless, the disease, with liver abscess as a frequent complication, occurs over the greater part of the United States and particularly along the Pacific sea board and in the southern states.

Pathology and Immunology of Amebic Dysentery in Relation to Chemotherapy.—Why *Amœba coli* contents itself with remaining on the surface of the intestinal mucosa while *Endamœba histolytica* and other pathogenic types burrow through the mucosa into the submucosa cannot be stated; but this mainly represents the difference between non-pathogenic and pathogenic organisms of this class. Practically nothing at all is known of the agencies by which *Endamœba histolytica* gains access to the deeper tissues with the production of inflammatory changes; I doubt if this is merely a matter of motility on the part of the parasites and surmize that these pathogenic species are capable of secreting a toxin producing cellular necrosis and that the organisms are thereby able to open up an avenue of infection for themselves without the necessity for minute traumatic breaks in the epithelial barrier of the mucosa. Furthermore, it would appear that these toxic substances, as well as the protoplasm of the parasites themselves, are capable of eliciting inflammatory changes, although the bacteria and especially *B. coli*, carried along with the amebas or following in their wake may contribute in large part to the suppurative changes and the production of the acute and chronic ulcers of the intestine so characteristic of the disease.

Sometimes the amebas gain access to the radicles of the portal vein and, being carried to the liver, produce hepatitis and abscesses; sometimes the branches of the mesenteric arteries are invaded with the production of thrombosis and abscesses have been known to occur in the spleen, salivary glands and even in the brain. Petzetakis[62] has recently described cases of amebic bronchitis in which this distribution by the general circulation is suggested, although in cases of this kind direct infestation by the endamebas of the mouth may be responsible; Hemburger[63] has recently described amebic infestments of the skin.

As a general rule, the parasites are to be found in the margins of the ulcers and abscesses rather deeply buried in the tissues and for this reason local applications by means of colonic irrigations may fail to reach them and completely sterilize the tissues; fortunately, however, these deeply placed organisms are reachable by emetin injected subcutaneously, until fibrosis begins to cut off capillaries and access of drugs in the blood to the parasites, which accounts in part for the chronicity of amebic dysentery.

From the standpoint of pathological tissue changes, therefore, amebic dysentery offers numerous obstacles to successful therapy. In the first place, local application, while helpful, may fail to reach and destroy the organisms deeply buried in the margins of the ulcers. In the second place, secondary bacterial infection of the ulcers with *B. coli* and other intestinal bacteria is always present and contributes in no small part to the chronicity of the lesions. In the third place, endamebas in necrotic or fibrotic tissue may escape destruction by emetin and thereby greatly prolong the infection. For these and less important reasons amebic dysentery is a dangerous infection and aways likely to pursue a chronic course, requiring prolonged treatment even after acute symptoms have subsided, since relapses are so likely to occur, unless energetic treatment is given in the early stages before extensive tissue destruction has taken place. But secondary bacterial infections, in my opinion, constitutes the most important reason why the emetin treatment of amebic dysentery has so frequently failed and why so many observers have reported poor results. As shown by Vedder and since amply confirmed, ipecac and emetin are probably not at all bactericidal *in vivo* and I doubt if the chemotherapy of amebic dysentery, and especially chronic dysentery, will ever be on a thoroughly satisfactory basis until we discover a way and means

for more successfully combating the secondary and associated bacterial infections. In pure amebic infestations, as in liver abscesses, and likewise in early dysentery before bacterial infection has become important, emetin has proved very efficacious and a notable achievement in the chemotherapy of this disease, thanks to the investigations of Vedder and Rogers.

Little or nothing is known of immunological changes in amebic infestations. Apparently, however, spontaneous and complete recovery from well developed amebic dysentery is quite uncommon. It would appear that our body cells are not capable of producing appreciable amounts of amebacidal antibodies and this is analogous to the lack of antibody-production in other protozoan infestations. Doubtless cases of minor infestation recover and escape from the disease altogether is of frequent occurrence, but these are due to fortuitous circumstances rather than to immunological resistance. Sellards and Leiva[64] have recently stated that clinical evidence is very convincing that normal individuals exhibit considerable natural resistance to *Endamœba histolytica;* certainly the lower animals are highly resistant, young kittens being the only animals successfully infested for experimental purposes. But just how much this is due to natural antibodies or other immunological agencies and how much to the acidity of the gastric juice or local factors in the colon capable of destroying the free or encysted endamebas, is difficult to state and remains to be determined. But at any rate, I believe clinical experience has shown that recovery from amebic dysentery is usually a long process when unaided by medicinal treatment and indicating that immunological destruction of the amebas does not reach a high degree of perfection.

Emetin in the Treatment of Amebic Dysentery.—Naturally a large number of compounds have been advocated from time to time for the treatment of amebic dysentery by oral administration or rectal injection, but since the investigations of Vedder,[65] none have commanded as much attention as ipecac and one of its alkaloids, emetin. Recently an arsenical compound stovarsol, has been reported upon favorably but I shall discuss this and other arsenicals shortly in the treatment of dysentery.

Vedder has shown that ipecac and emetin possess an extremely high amebacidal activity *in vitro* for cultures of limax amebae and essentially similar results have been reported by Wherry,[66] Rogers,[67] Ryman and Wenyon,[68] Smith and myself[69] and others for ameba in the mucus of dysenteric discharges and the gingival pus of Rigg's disease. Dilutions of emetin as high as 1:100,000 are capable of killing the trophozoites in exposures of at least an hour at 38°C. although, as shown by Wherry, encysted parasites are much more resistant. In other words the life cycles of the endamebas exert an important influence and the difficulty of destroying the encysted parasites is largely responsible for the chronicity and relapses of amebic diseases, being analogous to the resistance offered by the sexual forms of the malarial plasmodia and suggesting that it may be possible to combine emetin with a dye or some other substance better able to penetrate the cysts.

Apparently Dale and Dobell[70] were the first investigators to undertake seriously an investigation of the curative properties of emetin in experimental amebic dysentery in kittens. They were however, unable to eradicate the infection and, furthermore, kittens receiving prophylactic doses of emetin were successfully infected. Mayer[71] reported similar results but in a more recent study by Sellards and Leiva,[72] employing cats and kittens infected with *E. histolytica*, good results were observed with rectal injections of emetin and quinin hydrochlorid while pafaverin and an extract of *Castela nicholsoni* (Chaparra amargosa) proved unsatisfactory.

Rogers[73] was first to use and recommend subcutaneous and rectal injections of emetin in the treatment of the amebic dysenteries of man, being led to give the drug a trial by the results of Vedder's investigations. He had long advocated the use of ipecac in amebic disease, and in 1907 demonstrated that the same drug would rapidly cure an amebic hepatitis in the presuppurative stage, and thus prevent the formation of amebic liver abscesses. Having been convinced of the action of emetin on amebas *in vitro*, Rogers

decided to use emetin hypodermically, and in 1912 he reported 2 cases of severe amebic dysentery and 1 case of acute hepatitis which were rapidly cured as the result of this treatment. Rogers later published further experiences with emetin in the treatment of 12 cases of amebic disease including cases of acute amebic dysentery, chronic amebic dysentery, acute hepatitis in which the formation of pus was prevented by the use of emetin, and of amebic abscesses of the liver cured by aspiration and injection of emetin.

Since then a rather extensive literature has accumulated upon the subject which need not here be reviewed in detail, except to state that enthusiasm with respect to the success of emetin has waxed and waned from year to year, indicating that much is yet to be learned. I believe, however, that it may be conservatively stated that the results of these *in vitro* and *in vivo* experiments show that emetin and quinin are strongly amebacidal. The problem is to bring them in contact with the amebas, as they occur in the deeper tissues of the intestinal wall in the amebic dysenteries. Rectal injections of emetin are apparently more efficacious than subcutaneous injections, at least in experimental infestments, but yet the latter have undoubtedly yielded good results in many amebic cases of dysentery of human subjects. Rectal injections of quinin, however, are apparently better than rectal injections of emetin, because much less toxic while definitely amebacidal and slightly bactericidal. In brief the value of emetin in amebic dysentery and amebic abscesses of the liver, may be summarized somewhat as follows:

1. Particularly good results are to be expected in amebic abscesses of the liver or other organs secondary to dysentery. Surgical evacuation may be required, but results show that emetin may completely cure small abscesses at least and that it should always be given even in surgical cases. Evidently emetin is better able to reach the endamebas in these abscesses than in the intestinal wall, but a more important reason, in my opinion, is that mixed bacterial infections are less likely to occur, which greatly complicate the treatment of the intestinal ulcers.

2. Emetin by subcutaneous injection, by oral administration or by rectal injection is much more efficacious in the early than in the later stages of dysentery. This is to be expected, because secondary bacterial infection is not so extensive, necrotic tissue harboring and protecting amebas has not been produced and chronic fibrosis has not developed, all of which may interfere with the amebacidal activity of the drug.

3. Emetin is but feebly amebacidal for encysted *E. histolytica* and may not completely remove them from the bowel. For this reason the parasites may be found in the intestinal contents for long periods of time after clinical cure and produce relapses. On the other hand, the endamebas found under such circumstances may not be *E. histolytica*, but the fact remains that, as long as amebas are found, the danger of relapse is present.

4. Unquestionably the subcutaneous injection of emetin has greatly improved our treatment of amebic dysentery and particularly of the acute early cases; at least, the relief of symptoms is oftentimes wonderful and much better than with the older forms of treatment, although Vedder's hope that the drug would accomplish in dysentery what arsphenamin has done in syphilis has not been realized in most cases. There is much yet to be learned, but I repeat that, in my opinion, the difficulty of curing amebic dysentery and particularly of chronic dysentery is principally due to three factors: (*a*) secondary bacterial infection; (*b*) the difficulty of bringing emetin or quinin in contact with the deeply situated amebas in *all* ulcers of the colon by enemas of these drugs, and (*c*) the fact that emetin is too toxic by all routes of administration to permit the administration of sufficient amounts over a

sufficiently long period of time to destroy all of the parasites, particularly the encysted ones, in some cases of amebic dysentery, although enough may be given to afford symptomatic relief and to hold the disease in long periods of check and latency. Furthermore, emetin is so low in bactericidal activity as to be without any effect upon the secondary bacterial infections of amebic dysentery and is likewise useless in the treatment of bacillary dysentery.

Arsphenamin, Neoarsphenamin and Stovarsol in the Treatment of Amebic Dysentery.—It is no wonder that arsphenamin and neoarsphenamin should have been employed in the treatment of amebic dysentery and especially when it was discovered that these arsenicals were poisonous for trypanosomes, spirochetes and other protozoa. Unfortunately however, no one appears to have used these drugs in the treatment of experimentally produced amebic dysentery, so that an opinion of their value must be based alone upon clinical results.

But quite a large number of clinical reports by Win,[74] Willets,[75] Gunn,[76] Chalmers and Archibald,[77] Ravaut and Charpin[78] and others indicate that intravenous injections of arsphenamin and neoarsphenamin have been apparently beneficial in the treatment of amebic dysentery and carriers. Lawson, of Roanoke, informs me that he has found rectal infusions of arsphenamin (0.6 gm. dissolved in warm water without neutralization) of great help and he has also administered this compound in salol coated pills.

But recently Garin and Lepine[79] have employed stovarsol in the treatment of amebic dysentery and its complications with considerable success. The plan was to administer 0.5 to 0.75 gm. daily in capsules during the first and third weeks while emetin was given during the second and fourth weeks of treatment. Johns and Jamison[80] have reported exceptionally good results in the treatment of 46 cases of amebic dysentery by the oral administration of 0.5 to 1 gm. (8 to 15 grains) of stovarsol each day for three to six days in succession. Clinically the cases ranged from the acute fulminating infections to the chronic varieties and the treatment was found especially advantageous in the treatment of such difficult cases as patients with severe cardiac lesions, with the toxemia of pregnancy and in very small children. No relapses were noted over a period of observation of about four months.

Methods for the Specific Treatment of Amebic Dysentery.—Naturally many different methods have been advocated for the treatment of amebic dysentery but it is not possible to lay down any definite plan suitable for all cases as each individual case is a problem by itself. The following plan is offered only in the way of a suggestion likely to be applicable for the treatment of most cases:

1. The patient should be confined to bed and a cathartic given, one half ounce of Epsom salt or castor oil being especially efficacious. Very careful nursing is required with particular care of the mouth and skin, bed-sores being especially likely to occur in chronic cases if the buttocks are repeatedly soiled with the bowel discharges. A nurse especially experienced in giving colonic irrigations should be employed. Due care should be exercised in the disinfection of the discharges and soiled bed-clothes; also in the cleansing and disinfection of the hands.

2. During the acute stages a liquid diet is required and a generous milk diet is especially suitable, although a soft diet is permissible for most cases, due care being taken in the selection and amounts of food to minimize the residue, abdominal distress, flatulence and incomplete digestion. Plenty of cool plain water, seltzer water or diluted ginger ale may be given, the latter especially if nausea is present. In severe cases with dehydration of the tis-

sues the intravenous injection of 500 c.c. of saline solution is sometimes required.

3. Stovarsol may be first tried in dose of 0.5 gm. (7½ grains) in a capsule twice a day for three to six days. If the acute symptoms subside the dose may be reduced to one capsule per day for an additional week or two followed by careful examination of the feces for ameba at intervals over several months.

4. If stovarsol is not used or fails, treatment with emetin, quinin and bismuth may be undertaken somewhat as follows: (1) A large daily dose of bismuth subgallate (60 grains) suspended in water or milk; (2) two daily doses of 1 grain of emetin bismuth iodid in lightly keratinized capsules; (3) one or two daily subcutaneous or intramuscular injections of emetin hydrochlorid in dose of ⅓ grain; (4) a daily high colonic irrigation of 1:1000 quinin hydrochlorid in comfortably hot starch water. An arsphenamin irrigation prepared by dissolving 0.6 gm. in 1000 c.c. of water or 1:500 protargol may be used occasionally, but emetin enemas should not be given in view of the amounts administered by ingestion and injection. In very severe cases threatened with gangrenous colitis, appendicostomy with irrigation of the colon with quinin solution or 1:500 collargol may be required. Colonic irrigations with a pint to a quart of kerosene have been used successfully by Dowling and others; due care must be taken against irritation of the skin.

5. After the acute symptoms have subsided and usually within 10 to 12 days, the injections of emetin may be stopped while continuing with the daily doses of emetin bismuth iodid by ingestion and the colonic irrigations of quinin for another week.

6. The heart and circulation must be carefully watched while emetin is being given; strophanthus or digitalis may be administered if required and 0.5 to 1.0 c.c. of adrenalin chlorid by intramuscular injection if collapse occurs or is threatened.

7. The bowels may require castor oil every two or three days, being best given with a few drops of tincture of opium in soft capsules. Tenesmus may require no further treatment, but if severe, 30 drops of a 20-per cent. alcoholic solution of benzyl benzoate may be given once or twice a day; sometimes hot turpentine stupes or a hot water bottle over the abdomen are required and the former especially if there is colic and flatulence. Morphin should be avoided.

8. The stools should be carefully examined at frequent intervals for *E. histolytica* and especially for the encysted forms. If these are absent the administration of emetin bismuth iodid may be stopped, as likewise the colonic irrigations, or the administrations gradually reduced.

If encysted parasites are found associated with slight symptoms, emetin bismuth iodid may be continued in dose of 1 grain twice a day; but as a general rule, it is inadvisable to give a total of more than 40 grains without a rest of one or two weeks, this being necessary to avoid cumulative toxic effects. Quinin in dose of 5 grains, or 6 ounces of infusion of *Chaparro amargosa* (bitter bush), may be given twice a day before meals as substitutes. It is sometimes very difficult to get rid of this residual infestment and occasionally the encysted ameba are found over long periods of time without apparent lesions or symptoms. It is always advisable, however, to continue medication, since relapses are likely to occur as long as parasites are present. Stovarsol or arsphenamin are worthy of trial.

9. *Relapses* are treated in much the same manner as the initial attack, the choice of drugs and doses being guided according to the severity of the

lesions. Colonic irrigations with 1:1000 quinin are especially indicated, substituted now and again with irrigations of arsphenamin solution. A few intravenous injections of neoarsphenamin in dose of 0.6 gm. may be given; aside from the possible amebacidal effects, the arsenic may aid in improving the blood and nutrition. The matter of diet and physical regimen are very important in relation to the correction of the asthemic and neurasthemic states so likely to be present. Stovarsol may be tried.

10. To prevent late hepatic abscesses, Stitt recommends the intramuscular injection of 1 grain of emetin hydrochlorid daily for two or three days in succession each month, until the feces have been free of parasites for several months at least, when the danger is largely removed.

11. The treatment of chronic amebic dysentery presents many difficulties and is always tedious and prolonged. Stovarsol is worthy of trial in dose of 0.5 gm. in capsules two or three times a day. Emetin bismuth iodid may be given in dose of 2 grains in salol coated pills twice a day for two weeks at a time, interrupted by one or two weeks in order to avoid cumulative toxic effects; during this time 6 to 8 ounces of an infusion of *Chaparro amargosa* (bitter bush) may be given by mouth, one half hour before meals.

High colonic irrigations are especially useful, one or two being given each day. For this purpose one or two quarts of 1:1000 solution of quinin, infusion of *Chaparro amargosa*, 1:1000 silver nitrate or 1:500 protartol, may be employed. For ulcers reachable through the protoscope or sigmoidoscope, applications of 25-per cent. silver nitrate may be made.

To the best of my knowledge, carbon tetrachlorid has not yet been employed for the treatment of acute and chronic amebic dysentery, but in view of the excellent results observed in the treatment of hook-worm infestments with this substance, it may be worthy of trial in dose of 2 or 3 c.c. a day for two or three days in succession.

Specific Treatment of Amebic Liver Abscess.—It would appear that ipecac and emetin are indicated in all other clinical types of amebic diseases and especially in amebic abscesses of the liver when the chance of preventing them by early specific treatment has been lost. By open surgical drainage alone the mortality has been in the neighborhood of 57 per cent. Rogers[81] has recently stated that sterile aspiration of the contents followed by injection of a 1:50 solution of quinin dihydrochlorid combined with large doses of ipecac by mouth or emetin by injection, has reduced the mortality in 111 cases to about 15 per cent. or less. Certainly it would appear advisable to employ either ipecac or emetin in all cases in combination with appropriate surgical measures.

Specific Treatment of Oral Amebiasis.—As shown by Barrett and Smith[82] and independently by Bass and Johns,[83] *Endameba gingivalis* (Gros) may be found in smears of the secretions of pyorrhaea dentalis and alveolaris and possibly play an important rôle in the production of infection of the gums and alveolar processes. These endamebae have also been found in apparently healthy mouths, and it is not now generally believed that they are the primary cause of gingival infections but that the parasites by their digging and migratory habits, may carry bacteria and spirochetes into the deeper tissues and thereby open up avenues of infection and prove very important as a secondary etiological factor in these conditions. Rivas[84] states that he has found in the secretions of a case of gingivitis, endamebae closely resembling *E. histolytica* and if this should be confirmed, a more intimate relationship between oral and intestinal amebiases and even of amebic dysentery may be established.

Whenever the gingival secretions show the presence of amebas it is well to employ measures for their removal along with such surgical measures as may be required and the local application of solutions of arsphenamin and bactericides for the treatment of the more important spirochetic and bacterial infections, already discussed and described in Chapters VIII and XXXI.

Smith and Barrett have recommended the local application of 0.5 to 1-per cent. solutions of emetin, care being taken to introduce the solution into the pockets by means of a syringe fitted with a small curved, blunt needle. Bass and Johns have advocated the daily subcutaneous injection of emetin hydrochlorid in dose of ½ grain for three to six days in succession but local applications would appear sufficient in most cases.

Chemotherapy of Balantidic Dysentery.—Somewhat similar to the lesions and symptoms of amebic dysentery are those occasional dysenteries caused by the ciliates *Balantidium coli* and *Balantidium minuta*. These parasites are especially found in hogs and while originally regarded by Malsmsten, Doflein and others as harmless commensals of man, the investigations of Strong[85] and Solowjew[86] have definitely proved that they may burrow into the mucosa of the colon and in conjunction with bacteria produce an ulcerative colitis with lesions and symptoms similar to those of amebic dysentery.

The parasites are found by examination of the stools and, while they may be present without apparent lesions or symptoms, yet their presence is fraught with danger. The parasites are capable of encystment like *E. histolytica*, which adds greatly to the difficulty of removing them by medicinal measures.

The disease is most common in the tropical and subtropical countries, but many cases have been reported in the United States. Glaessner[87] states that the parasites contain a hemolytic toxin analogous to the hemotoxins of other parasitic worms as described by Schwartz[88] and others. Abscesses of the liver have been described, due to the entrance of the parasites into the portal veins.

The treatment of balantidic dysentery is usually difficult and unsatisfactory. To the best of my knowledge, no systematic chemotherapeutic investigations have been made, probably because of the difficulty of reproducing the disease experimentally, although it is claimed that kittens and adult cats can be infested by colonic injections of fecal material containing the parasites. Dutcher[89] reports that intravenous injections of arsphenamin once a week for a series of 3 to 6 injections, have proved of great value; at least large numbers of parasites were discharged in the feces with prompt improvement of the anemia. Ipecac and emetin, so efficient in amebic dysentery, are apparently useless in this infestment; tartar emetic has likewise failed. Thymol has been apparently successful in some cases. Colonic irrigations with tannic acid, vinegar, kerosene, protargol, quinin, etc., may be helpful.

Greene and Scully have reported that simply placing the patient on a milk diet may be sufficient for recovery; apparently the milk produces a medium unfavorable for the parasites and at the same time furnishes fluid for the desiccated tissues while being without irritation for the inflamed intestinal mucosa. They give 2½ quarts of whole milk per day divided into small portions at regular intervals. After several days the milk is supplemented by the addition of one or two soft eggs and later, when the bowels become sluggish, by stewed fruits. Bismuth subnitrate is given during the first day or two to check the diarrhea.

If these simple measures fail it would appear worth while to inject arsphenamin or neoarsphenamin intravenously once a week. Salol coated pills of arsphenamin may also be given; thymol by stomach may prove

helpful as likewise capsules of 1 to 2 grains of methylene-blue. I believe one or two doses of 2 to 3 c.c. of carbon tetrachlorid by stomach may be worthy of trial; possibly colonic irrigations with this substance may be more efficacious although great care must be exercised against absorption of toxic amounts and the production of local irritation. Possibly colonic irrigations with 1:2000 solution of thymol may be useful, as they have been found efficacious for the removal of *Lamblia intestinalis*, another parasitic infestment shortly to be discussed. Colonic injections of kerosene may be tried; likewise irrigations with 1:1000 quinin, 1:3000 methylene-blue or 1:500 protargol.

Chemotherapy of Lambliasis or Giardiasis.—Infestment of the intestines with *Lamblia intestinalis* may produce no discernible lesions or symptoms, the presence of the parasites being detected by routine examination of the feces or duodenal contents (Lyon-Meltzer method). But as recently stated by Musgrave,[90] a chronic diarrhea with intermittent exacerbations, digestive disturbances and nervous symptoms may be produced, the infestment being particularly severe in children, quite common in the tropics, and variously designated as flagellate diarrhea, tropical diarrhea and monad diarrhea. The disease, however, is not confined to tropical countries, but is world-wide in distribution; I have seen several cases in Philadelphia during the past four years. It was particularly prevalent during the World War, being generally known as trench diarrhea.

Death rarely results from *Lamblia* infestment and consequently very little is known of the pathological changes, but available evidence indicates that the parasites may produce a catarrhal enteritis involving the small intestine and, either primarily or as secondary invaders, aggravate lesions of the intestine by other agents. The flagellate forms are limited to the small intestine except in diarrhea, when they are found in the colon and feces; the encysted forms are regularly found in the feces and may reach the liver with the production of abscesses. Musgrave states that he has encountered no instance of prolonged parasitism without symptoms, the characteristic symptom being a persistent diarrhea. Constipation, however, may be present rather than diarrhea and the parasites have been known to invade the gall-bladder; Kantor suggests that *Lamblia* cholecystitis may be a definite clinical entity. Abdominal pain of varying degree is usually present in all cases presenting symptoms.

A few systematic investigations in the chemotherapy of the disease have been made and especially with arsphenamin and neoarsphenamin. It is stated that mice may be experimentally infested by fresh human material; I have failed to successfully infest white rats and guinea-pigs. Kofoid, Boeck, Minnick and Rogers[91] state, however, that rats may be naturally infested with a species of *Giardia* quite similar to *Lamblia intestinalis* and they have found that massive doses of neoarsphenamin (4 to 8 times larger per kilogram than given to human beings) may stop cyst formation and bring about a disappearance of the parasites; ordinary single doses, however, were without effect. Yakimoff and his colleagues[92] had previously shown, in 1917, that mice experimentally infested with *Giardia* may be cured by injections of 1 c.c. of 1:300 to 1:1000 solutions of neoarsphenamin per 20 grams of weight corresponding to 0.005 to 0.015 gm. per kilo or 0.3 to 0.9 gm. for an adult of average weight.

Cade and Hollande,[93] however, failed to cure the infestment by administering arsphenamin by mouth; emetin subcutaneously, quinin sulphat and picric acid also failed. Goiffon and Roux,[94] Mantovani,[95] McGill,[96] Hollander[97] and others, also obtained indifferent results with arsphenamin and neoarsphenamin, but, as indicated by the reports of Carr and Chandler,[98] Kantor,[99] Reverdin and Chomé[100] and Simon,[101] the failure of arsphenamin and neoarsphenamin may have been due to the administration of too small doses; the latter also employed duodenal lavage with these arsenicals with success. Lyon and Swalm[110a] have recently reviewed the literature very carefully and state that intraduodenal injections of magnesium sulphat and 100 c.c. of 2 to 4 per cent. solutions of dimol may be effective for removing the parasites in the duodenum but without any effect upon those in

the biliary passages. Owing to the frequency of relapses they advise against drawing too hasty conclusions regarding any method of treatment. I would suggest the oral administration of carbon tetrachlorid or tetrachlorethylene as described on page 425, since these are known to be effective in the treatment of helminthiasis and especially hook-worm infestments.

Treatment with arsphenamin and neoarsphenamin, therefore, has offered more encouragement than any other drug; emetin, quinin, methylene-blue, tartar emetic, chloroform, sulphur, duodenal lavage with magnesium sulphat, Jutte's solution (0.9-per cent. sodium sulphate and sodium chlorid) and decinormal hydrochloric acid, etc., have all failed. Apparently the arsenic eliminated in the bile may be toxic for the parasites providing the concentration is sufficiently high and the following treatment may be found useful: (*a*) The intravenous injection of 0.6 to 0.9 gm. of neoarsphenamin every five days for 3 or 4 doses; (*b*) duodenal lavage with 100 c.c. of a 1-per cent. solution of neoarsphenamin if biliary drainage (Lyon-Meltzer method) is being given; (*c*) the internal administration of thymol in dose of 0.25 to 0.5 gm. (4 to 8 grains) in capsules with lactose and (*d*) enemas of 1:2000 solution of thymol, as recommended by Musgrave. While the parasites may disappear for a while, cure of the infestment cannot be regarded as accomplished until repeated and careful examinations of the feces or duodenal contents and bile have yielded negative results over a period of several months at least and preferably for a year or two. Stovarsol in dose of about 0.5 gm. per day has also been reported as yielding successful results in the treatment of *Lamblia* and *Trichomonas* infestments.

Chemotherapy of Trichomoniasis and Other Flagellate Infestments.—As is well known, the intestines and less frequently the stomach, mouth, respiratory tract, vagina, bladder and other organs may be infested by a species of the genus *Trichomonas*, characterized by no definite symptoms or by those due to local irritation. *Trichomonas intestinalis* is generally regarded as capable of producing diarrheal conditions in the tropics and respiratory and genito-urinary trichomoniasis may produce symptoms.

Nothing has been done, however, in the way of chemotherapeutic investigations in these infestments. The parasites are difficult to remove and vigorous measures are not required or indicated in the absence of symptoms. The same may be stated in relation to *tetramitiasis*, *chilomastixiasis*, *cercomoniasis* and *prowazekiasis;* if treatment is demanded, it may be along the lines discussed above for giardiasis.

Chemotherapy of Piroplasmosis or Babesiosis.—Before concluding this account of the chemotherapy of protozoan diseases, brief mention may be made of diseases of the lower animals caused by sporozoa belonging to the genus *Babesia*, or *Piroplasm*. The parasites infest the red blood corpuscles and three forms are especially well known, namely, *Babesia canis* (Piana and Galli-Vallerio), infesting dogs, *Babesia bigemina* (Smith and Kilbourne), infesting cattle and producing Texas cattle fever, and *Babesia bovis* (Babes) producing disease of cattle in Europe. Similar parasites have been found in the blood of sheep (*B. ovis*) and horses (*B. equi*).

These diseases, and especially babesia of dogs, are of great interest because they were very early the subject of chemotherapeutic investigations. Thus in 1909, Nuttal and Hadwen[102] found subcutaneous injections of 6 to 10 c.c. of 1-per cent. solutions of trypan-red and 5 to 10 c.c. of saturated solutions of trypan-blue, of some value in canine piroplasmosis; Theiler[103] and more recently Urbain[104] have likewise found trypan-blue of some value. Meyer[105] found trypan-red of no value in babesia of dogs (bilious fever or malignant jaundice), but trypan-blue demonstrated some degree of parasiticidal activity

in four animals. Nuttal and Graham-Smith have found quinin, tartar emetic, methylene-blue, etc., of no value. The pentavalent arsenicals, like atoxyl, sodium methyl arsonate, etc., have likewise proved without effect in babesia of both dogs and cattle; likewise arsacetin and sodium-para-amino phenylarsonate (soamin), and Nawrotski and others have stated that arsphenamin is without appreciable effect. Hutyra and Marek[106] have fully reviewed the literature on the treatment of piroplasmosis of dogs, horses, cattle and sheep, and those interested in these subjects are referred to this excellent work for a résumé of the subject up to 1922. I believe that stovarsol by mouth in dose of 0.02 gm. per kilo may be worthy of trial.

Chemotherapy of Coccidiosis.—At least three species of *Coccidia* have been found to be parasitic in man: (1) *Coccidium cuniculi* of rabbits; (2) *Coccidium hominis* and (3) *Coccidium bigemini.* The parasites invade the epithelial cells or villi of the intestine and the cells and ducts of the liver. Ottolenghi and Pabis[107] have infected young rabbits experimentally, and treated them with atoxyl, arsenophenylglycin and tartar emetic with negative results; otherwise, however, chemotherapeutic investigations do not appear to have been made although the subject urgently requires investigation. While *coccidiodal granuloma* is a different disease etiologically, brief mention may be made of it at this time. This infection is not of protozoon origin but is caused by a fungus or mold sometimes placed in the class of Ascomycetes. It is also known as *Blastomycosis coccidioides* and the disease has been described under the name of blastomycosis in some localities and sporotrichiosis in others. It is a striking fact that the majority of cases of coccidiodal granuloma have occurred in males living in California or in females who had lived in this state and particularly in the San Joaquin Valley. Nothing definite is known of the mode of transmission. In the majority of cases the atrium of infection seems to be the respiratory tract with the production of lesions in the lungs and glands resembling those of tuberculosis. In a few instances gastrointestinal, joint and skin lesions have occurred. Potassium iodid has been employed in treatment but with little or no success; to the best of my knowledge there has been developed so far no efficient method of treatment and the subject is deserving of investigation from the chemotherapeutic standpoint.

Chemotherapy of Schistosomiasis or Bilharziasis.—Since several of the parasitic trematodes are known to infest the blood-vessels and especially the portal venous system, whence the parasites and especially the eggs may be transported to the bladder, rectum, liver, lungs and other organs, many and early attempts have been made to destroy them by the administration of drugs by intravenous injection. Infestations with these parasitic trematodes may be designated with the general terms *schistosomiasis, bilharziasis or distomiasis.* The diseases so grouped are much more commonly encountered among the lower animals. But at least five of them occur in human beings in tropical and subtropical countries, where transmission is especially facilitated by unhygienic conditions, and where the high incidence and serious lesions and symptoms produced render them of great importance.

Naturally tartar emetic and other antimonyls have been widely employed because of the success attending their use in protozoan diseases, and since ipecac and especially emetin have proved so efficacious in amebiases. Arsphenamin and its substitutes have also been tried and, while a few of the earlier reports were encouraging, we now know that these arsenicals are without much effect upon the metazoa.

Clinical Varieties of Schistosomiasis.—Of the parasitic trematodes infesting the blood and blood-vessels of man and the lower animals or occasionally transported by the blood to organs or tissues not usually inhabited by them (the erratic trematodes), particular interest is attached to the following from the standpoint of specific therapy:

1. *Urinary schistosomiasis or bilharziasis* caused by the adult worm and eggs of *Schistosoma hæmatobium.* This parasite inhabits the portal venous system and its branches; also the small veins of the pelvis and rarely the vena cava and lungs. The females, however, are especially apt to migrate to the veins of the bladder where they and the eggs produce a disease characterized chiefly by periodic attacks of hematuria and cystitis.

2. *Intestinal schistosomiasis* or *bilharziasis,* caused by the adult worm and eggs of *Schistosoma mansoni.* The worms live in the portal vein but migrate to the intestines and especially the rectum in the capillaries of which they lay their eggs, which burst these vessels and escape into the mucosa, producing ulcers (schistosomic dysentery and fever), extensive granulomata (schistosomic tumors), etc.

3. *Hepatic distomiasis,* or *schistosomiasis japonica,* caused by the worm and eggs of *Schistosoma japonicum.* This disease is also known as "Katayama disease" or "dysenteric schistosomiasis." The adult parasite lives in the veins and arteries of the liver and in the mesenteric and pelvic veins. The eggs may be found in the liver, but more frequently in the lymph-glands of the pelvis and submucosa of the rectum, producing painful enlargements of the liver and spleen, with or without fever, urticarial and dysenteric lesions, anasarca, anemia and sometimes pulmonary and cerebral lesions.

4. *Pulmonary distomiasis* or *paragonimiasis,* caused by *Paragonimus westermani* (*ringeri*). The worm usually inhabits the lungs, but has been known to occur in the liver and other organs, when finding its way into the blood followed by general distribution produces a variety of clinical types of the disease, as the generalized, thoracic (pulmonary), abdominal (hepatic and intestinal) and cerebral types.

In addition to these, we may add the diseases produced by *Fasciola hepatica* and *Fasciola gigantica,* very common fluke infestations of the lower animals and especially found in the liver of sheep ("sheep-rot"), but occasionally found in man and especially in the lungs. In some manner, however, the parasites may gain access to the blood and have been found in the liver, the portal vein and its branches, the anterior tibial vein, subcutaneous tissue, the pharynx (producing a disease of North Lebanon called "halzoun"), etc. As shown by Christopherson,[108] the worms have a potential longevity in the tissues, displaying considerable energy throughout their (frequently) long life, traversing the portal vein between the liver and bladder or rectum. Their generative energy appears to be great, commencing early and continuing through life with the deposition of enormous numbers of eggs.

Experimental Schistosomiasis.—Bettencourt and Borges[109] report that adult *Schistosomas* appearing to be *S. hæmatobium,* have developed in mice experimentally infected with larvae and cercaria from snails taken from an area of endemic schistosomiasis in Portugal. This opens up a field for experimental chemotherapeutic investigation, although it would appear that the treatment of various types of bilharziasis has been satisfactorily solved by the administration of emetin hydrochlorid and tartar emetic. Fairley[110] has likewise experimentally infected animals with *S. spindalis* and reports that, while tartar emetic and urea stibamin failed to cure, absolutely specific cures were secured by intravenous injections of emetin hydrochlorid.

Specific Treatment of Bilharziasis.—While arsphenamin was at one time thought to be curative, the studies of Day and Richards,[111] Fulleborn and Werner[112] and others have since proved the arsenicals to be valueless.

But excellent and specific results have been observed following injections of emetin, Reguzis[113] stating that he was first to use the drug by intravenous injection in the treatment of *Bilharzia hematobium* infestments in Cairo, Egypt. Bonnet[114] and Tsykalos[115] have also reported excellent results with this drug, the latter injecting 0.02 to 0.010 gm. every two or three days for 6 injections followed by an intermission of six days and a second series of 6 injections in dose of 0.010 gm. No living parasites or living ova could be found after the fifteenth injection.

But apparently much better results have been secured by intravenous injections of tartar emetic, first introduced by Christopherson,[116] about 30 grains (0.180 gm.) in divided doses over a period of twenty-eight to thirty days, being sufficient. Pavy,[117] Quintini,[118] Petillo,[119] Tyau,[120] Libby,[121] Lasbrey and Coleman[122] and especially Cawston,[123] have reported

uniformly successful results with this compound. The treatment may be conducted as follows:

The injections (intravenous) are given on alternate days over a period of from fifteen to thirty days. The first dose is ½ grain (0.03 gm. of antimony and potassium tartrate dissolved in 90 minims (6 c.c.) of sterile physiologic sodium chlorid solution. The injection is repeated every other day and increased by ½ grain up to a maximum of 2½ grains (0.16 gm.) at a single sitting. In giving the larger doses, the total amount of an injection is made up to 10 c.c. with the diluting fluid. The total amount of the drug injected may amount to between 20 and 30 grains (from 1.3 to 2 gm.). Manson says that this amount may be shown by further observation to be too large. A rapid improvement occurs in the condition of the urine and after about 15 grains (1 gm.) has been injected all traces of blood usually disappear. Care must be taken that none of the solution escapes into the surrounding tissues, as an abscess may result. It is advisable to have the patient lie down for a few hours after an injection. A total of 10 grains (0.6 gm.) appears sufficient for children.

Emetin also has recently been given with apparent success. It is advocated for patients who are intolerant of antimony. It may be given intramuscularly, but whenever possible should be given intravenously in a 3-per cent. solution in sterile water, the dose being 2 c.c. containing 1 grain (0.06 gm.) of emetin hydrochlorid. The maximum single dose is 3 grains (0.2 gm.) for an adult. Generally one commences with ½ grain doses. A total of from 15 to 20 grains (1 to 1.3 gm.) may be given altogether.

Both drugs apparently act upon the ova especially since these show degenerative changes. They also probably affect the adult worms which gradually die off. The newer antimonyls, as employed by Randall in the treatment of granuloma inguinale, do not appear to have been used, but probably will yield equally good and even better results, since they appear to be less toxic than tartar emetic.

Specific Treatment of Fasciolopsis.—But the results observed in the treatment of fluke infestations have not been as good. Mauriac and Boyer[124] report the failure of emetin, tartar emetic, thymol, neoarsphenamin and male fern in the treatment of infestments of sheep and one human being. Since infestations of the liver and lungs are very frequent and especially in China, these diseases urgently call for systematic chemotherapeutic investigation.

Arsphenamin, Neoarsphenamin and Tartar Emetic in the Treatment of Trichinosis.—A very large number of drugs have been employed in the treatment of trichinosis, due to infestment of the muscles and other tissues, even of the spinal fluid, with *Trichina spiralis*. In 1914, Van Cott and Lintz[125] reported unsuccessful results in treatment with intravenous injections of arsphenamin, but McNerthney and McNerthney[126] have reported an apparently successful result from the intravenous injection of 0.6 gm. of neoarsphenamin. Alexander[127] likewise reports negative results in the treatment of three cases with injections of arsphenamin, but Nieto,[128] has recently reported uniform success with 2 or 3 injections of neoarsphenamin in dose of 0.45 gm. each. It would appear, therefore, that neoarsphenamin is at least worthy of trial and that two or three intravenous injections of 0.6 gm. each at intervals of five or six days may afford temporary relief if not complete cure. Grove[129] has recently reported the apparently successful treatment of a case by intravenous injections of freshly prepared 2 per cent. solutions of tartar emetic in dose of 3 to 4 c.c. for every 10 pounds of weight, gradually increased to 10 c.c., every second or third day.

Specific Treatment of Uncinariasis, Other Intestinal Infestments and Filariasis.—It is hardly necessary for me to discuss here the treatment of other forms of intestinal infestations with the various tape and round worms, although strictly speaking, this subject belongs to the domain of chemotherapy, since drugs are given for the purpose of poisoning the parasites without the absorption of sufficient amounts to produce toxic symptoms. I must mention, however, the excellent results being observed at present with the internal administration of carbon tetrachlorid in the treatment of uncinariasis (hook-worm disease) as discovered by Dr. Hall of the Bureau of Animal Industry of the U. S. Department of Agriculture.[130] He found that 0.3 c.c. of the drug for every kilogram of body weight sufficed to expel all the hookworms without subsequent purgation—a result that he had not been able to achieve with any other anthelmintic. Tests of the drug made in combination with thymol and with chenopodium produced equally favorable results. Monkeys, swine and horses were also treated, and postmortem examinations performed on these animals, months later, revealed no pathologic changes in the organs which could be attributed to carbon tetrachlorid. Dr. Hall himself took 3 c.c. of the drug without ill effects and Wells[131] has made a recent and thorough study of the absorption and excretion of carbon tetrachlorid from isolated intestinal loops of dogs.

Lambert[132] has reported particularly favorable results covering 50,000 treatments in Siwa, Fiji. The drug is practically tasteless but has a faint odor and produces a sensation of heat after being swallowed. He reports three fatalities due to impure compounds. Meyer and Pessoa[133] have likewise described histological changes in the liver and kidneys of dogs ascribed to over dosage and toxic effects. But the amounts now employed are regarded as quite harmless and if due care is exercised in the use of a pure compound, the danger of toxic effects is greatly reduced but not entirely removed. Lambert states that "the symptoms seemed to depend on the amount of absorption of the drug by the human host. The drug itself is a purge when taken in sufficient dosage on an empty stomach. The purgative action seemed to be diminished or lost, however, when the medicine was taken by one suffering from constipation, or when food has been taken just before or just after the drug. It is in these cases that symptoms of absorption occurred. These symptoms seem to be the same as those exhibited by a person recovering from chloroform anesthesia. The commonest is a dull headache, which may last for two or three days and is best relieved by free purging with magnesium sulphate. A few patients reported nausea and vomiting; many were sleepy for several hours after taking the medicine, and a few who followed directions to the letter said that they had suffered from headache. Since magnesium sulphate has been given as a routine measure headache symptoms have rarely been reported. With the cases under control, no symptoms are ever heard of."

The dose is about 0.2 c.c. (3 minims) for each year of age up to 15 years, when the adult dose of 2 or 3 c.c. is reached. The drug is placed on a tablespoon or in a small glass, covered with water and swallowed. When young children are also infested with *Ascaris*, it is well to use oil of chenopodium at the same time, Lambert adding one part of chenopodium to eleven parts of carbon tetrachlorid. The dose of the mixture remains at 3 minims (0.2 c.c.) for each year of age. This means $2\frac{3}{4}$ minims of tetrachlorid and $\frac{1}{4}$ minim of chenopodium for each year. He has now treated with this dosage several hundred persons, many of whom have had fairly severe *Ascaris* infections. The worms have all been removed dead. The mixture is not disagreeable to take, and children have not objected to it. The oil is held in a perfect solution in the tetrachlorid. The drugs may quite properly be given in the same proportions to adults in the accepted dosage of from 50 to 60 minims (3 to 4 c.c.).

Pregnant women may be treated with safety, but alcoholism increases the toxicity of the drug.

Lambert states that carbon tetrachlorid in the dosage here given is not so effective a vermifuge as oil or chenopodium for removing *Ascaris*, only

40 per cent. of the parasites being removed by the Fijian tests. The drug occasionally removes *Trichocephalus dispar* in small numbers, but it does not cure the disease. It seems, however, to remove *Oxyuris vermicularis* in large numbers. Recently Hall and Shillinger[133a] have reported that *tetrachlorethylene* may be slightly more effective than carbon tetrachlorid, the dose being from 2 to 3 c.c. for an adult.

Both carbon tetrachlorid and tetrachlorethylene have also been used with success for the removal of hookworms and round worms of dogs, being administered in doses of 3 to 16 minims in soluble gelatin capsules.

Practically nothing has been accomplished in the chemotherapy of *filariasis* of human beings and the lower animals. Arsphenamin and neoarsphenamin have occasionally yielded apparently encouraging results and may be worthy of trial, but atoxyl, arsacetin, arsenophenylglycin, emetin, tartar emetic, trypan-blue, etc., have yielded negative results and especially in the lower animals, the literature being summarized by Hutyra and Marek previously quoted. It would appear that intravenous injections of antimony thioglycollamide every two days is justifiable, the adult dose being 0.08 gm. dissolved in 20 c.c. of sterile distilled water. Recently Rose[134] has reported that intravenous injections of "Bayer 205" in dose of 1 gram dissolved in about 10 c.c. of sterile water, caused a sharp initial increase of embryos in the blood, followed by a pronounced fall, which was however, only temporary, though sometimes noted from time to time for 2 or 3 months. These effects appeared to be produced through some toxic action on the parent worm, and not on the embryos.

PART VI

CHEMOTHERAPY OF DISEASES OF DOUBTFUL OR UNKNOWN ETIOLOGY

CHAPTER XXXIV

CHEMOTHERAPY OF THE ANEMIAS, MALIGNANT TUMORS AND OTHER DISEASES OF DOUBTFUL OR UNKNOWN ETIOLOGY OF MAN AND THE LOWER ANIMALS

There is scarcely a single acute disease of unknown or doubtful etiology in human beings in the treatment of which arsphenamin or its substitutes have not been tried; in the lower animals, these and the more toxic pentavalent compounds, like atoxyl, arsacetin and arsenophenylglycin, have also been tried, as well as a number of synthetic dyes. Aside from the possible parasiticidal effects, arsphenamin and neoarsphenamin may be expected to improve the metabolism and nutrition, at least temporarily and to a slight degree, and I am inclined to believe that these have been used as the basis for not a few reports of favorable curative effects, especially early reports shortly after the discovery of these compounds, which have not been generally confirmed. I suppose it is a rather common frailty of human nature for both patient and physician to note every apparent improvement with painstaking attention and enthusiasm whenever a new drug is under investigation and especially one that has promise of being "specific;" as a result some evidence of improvement is claimed with a too hasty publication of what may be nothing more than temporary improvement or favorable impressions.

Basis of Chemotherapeutic Investigations in Diseases of Doubtful or Unknown Etiology.—Upon first thought it would appear a useless expenditure of time and effort to endeavor to develop a chemotherapy for diseases of unknown or doubtful etiology. But this is far from being true in at least those acute diseases possessing all the characteristics of specific infections. Furthermore, some of these, like rabies, hog-cholera, small-pox, etc., occur in, or are readily transmissible to, the lower animals, thereby opening up a favorable avenue for laboratory research. It is true that chemotherapeutic investigations in such diseases are hampered, since the nature of the infectious agent is unknown, but they are not entirely hopeless or necessarily doomed to failure. In some instances the human disease has its counterpart in a disease of the lower animals; rabies is an example and possibly likewise the various malignant growths of rats and mice which are inoculable at will on a large scale. It must be admitted, however, that a disease of human beings not transferable to the lower animals is unfavorable for chemotherapeutic research, since clinical or empirical investigations in chemotherapy are seldom as satisfactory as those based upon preceding fundamental studies with the lower animals. But this applies equally well to those diseases of both

known and unknown etiology. In other words, we are still so ignorant of many of the fundamental principles of chemotherapy, insofar as the laws governing the relation being chemical constitution and the biological reactions of organotropism and parasitropism are concerned, that the whole subject is still largely a "hit or miss" proposition. But most progress is to be expected in those infectious diseases of known etiology transmissible to the lower animals and especially those of small size like the rabbit, guinea-pig, rat and mouse; next, with those of unknown or doubtful etiology but yet transmissible to the lower animals, and least with those of unknown etiology and apparently not transmissible to the lower animals. Even in the last-mentioned group, however, we can at least determine the important pharmacological and toxicological properties of compounds in the lower animals and use them empirically with the hope of accomplishing good while doing no harm.

While chemotherapeutic investigation is mainly applicable to those diseases of doubtful or unknown etiology, but known or strongly suspected of being infectious or contagious and thereby parasitic, yet the subject is not without interest in relation to the treatment of some known not to be infectious. In other words, a remedy may be employed for the *relief of symptoms*, even though it does not destroy or remove the cause. Arsphenamin, for example, has been used with some success in the treatment of anemias of apparently non-parasitic origin, pellagra, etc.; quinin and other alkaloids of cinchona bark are known to have a field of usefulness beyond the treatment of malaria, and emetin, tartar emetic, etc., are useful in diseases other than those of protozoal or metazoan origin. In other words, compounds easily qualifying for the honor of being classified as "specifics" may possess certain other general pharmacological properties of value in the relief of symptoms, even though they may not cure in the strict sense of eradicating the known or unknown cause of disease.

Chemotherapy of the Anemias.—Since Bramwell, in 1825, announced the beneficial use of arsenic in the treatment of pernicious anemia, Fowler's solution and other arsenical preparations have been constantly employed. With the discovery of atoxyl, arsacetin and other organic compounds, it was no wonder that these should have been used but never on a large scale because of their toxicity. Shortly after the discovery of arsphenamin, however, interest in this subject was greatly renewed and in 1911 Bramwell[1] reported on the treatment of two cases of pernicious anemia with intramuscular injections, followed in 1913 by a report on his experience with twelve cases, two of whom showed no change, three slight improvement and seven greatly benefited, one of whom later had a relapse. Since then a very large literature has accumulated upon the subject of the treatment of pernicious and other types of anemia with arsphenamin, neoarsphenamin and more recently, germanium dioxid, with many conflicting opinions of their value.

Mechanism of Therapeutic Activity of Arsphenamin and Its Substitutes in the Anemias.—If arsphenamin and its substitutes, or any other agent of reputed value in the treatment of anemia, are actually helpful, it must be in one or more of the following ways: (*a*) By the destruction of the parasitic agent producing the anemia, as *Sp. pallida* in syphilitic anemia; (*b*) by stimulating the bone marrow and other erythroblastic tissues; (*c*) by increasing the resistance of erythrocytes to hemolytic agents and (*d*) by promoting the elimination or neutralization of hemolytic or depressing agents, as the influence of arsphenamin in the correction of the depressing effects of mercurialization.

That arsphenamin and neoarsphenamin are capable of correcting the secondary anemia of syphilis is well known, and this is doubtless due to the destruction of *Sp. pallida* which apparently produces a hemotoxin and especially during the acute early stages of the disease. The same may be true, but to a much lesser extent, in the anemias caused by other microparasites, as the streptococcus and staphylococcus, if it is granted that these arsenicals possess some degree of bactericidal activity *in vivo*, which may be the case in streptococcus infection.

Whether or not arsphenamin and neoarsphenamin actually stimulate the bone marrow cannot be definitely stated, but I believe that such is probably the case in at least some instances of secondary anemia. Intravenous injections of rats and rabbits with arsphenamin, corresponding to 0.01 gm. per kilo, and neoarsphenamin, in dose of 0.02 gm. per kilo, have sometimes been followed by a slight leukocytosis with a slight drop in erythrocytes and hemoglobin during the following three hours, followed by a return to normal proportions within twelve to twenty-four hours. But I have never been able to increase definitely the erythrocytes above normal proportions in these animals by one to four injections of either drug in the doses mentioned, which corresponded to those given adult human beings of average weight; neither have I been able to elicit definite histological evidences of increased blood corpuscle formation in sections of the marrow of the long bones. It may be that arsphenamin and neoarsphenamin actually stimulate red blood corpuscles and hemoglobin production; indeed, I believe this does happen in some of the anemias over a brief period at least, but I have not been able to detect any increase in normal rabbits and rats or in human beings with approximately normal erythrocyte counts and hemoglobin estimations. That the leukocyte producing tissues are affected is indicated by the temporary leukocytosis sometimes following injections; also by those occasional accidents to these tissues with the production of asplastic anemias described in Chapter LI. Furthermore, I have observed a slight drop in the erythrocytes of syphilitic subjects within a few hours after the intravenous injection of 0.6 gm. arsphenamin in 150 c.c. alkaline solution, which may have been due to the effects of hemolysis, but I have not been able to detect a similar effect from the intravenous injection of 0.6 to 0.9 gm. of neoarsphenamin in 10 to 20 c.c. of sterile water.

In my experiments the repeated intravenous injection of arsphenamin and neoarsphenamin has had no influence upon increasing the resistance of the erythrocytes of rabbits, guinea-pigs and white rats to hypotonic saline and saponin solutions. But I have observed in three cases of severe syphilitic anemia a gradual return of the corpuscles to normal minimal and maximal resistance to hypotonic saline solutions, being analogous in this respect to the influence of arsenic upon non-specific resistance described by Hill[2] and others, but I am inclined to believe that these effects were due to the production of healthier erythrocytes as spirochetes were removed from the tissues, rather than to an actual increased resistance of the erythrocytes to hemolytic agents induced by the arsenic of arsphenamin or neoarsphenamin.

Just how arsenic, and especially arsphenamin and neoarsphenamin, tends to improve anemic states through an influence upon metabolism and elimination is difficult to state, but possibly this influence is exerted through the checking of oxidation with improvement in nutrition and weight. At least, the effects of arsphenamin and its substitutes are sometimes wonderful in cases of syphilis overdosed with mercury and presenting haggard and anemic states. Likewise, in the chloro-anemias of latent tuberculosis, constipation, cancer and in "indoor anemias," I have observed slight but definite improvement following small doses of neoarsphenamin by intravenous injection along with improved appetite and sometimes slight increase of weight and nutrition; but whether these effects are due to the influence of arsenic upon metabolism or to a stimulation of the blood-making organs cannot be stated. As mentioned in previous chapters it would appear that tryparsamid is even more efficacious than arsphenamin or neoarsphenamin in improving weight and nutrition, at least in cases of neurosyphilis.

Arsphenamin and Its Substitutes in the Treatment of Syphilitic Anemia.—Fournier in reviewing the anemias of syphilis states the disease may cause a diminution in the percentage of hemoglobin, a decrease in the number of erythrocytes and an increase in the number of leukocytes. He recognized five types of anemia in association with the disease: (1) the simple secondary anemia (the most common); (2) chorotic anemia; (3) chorotic anemia with leukocytosis; (4) leukemia and (5) syphilis imitating the picture of pernicious

anemia. He referred to the difficulty in some cases of deciding whether syphilis is the direct cause of the anemias or whether they are the result of associated symptoms, superimposed infections or misguided therapy. He quoted the old saying that "mercury is the iron of syphilitic anemia," but realized that while mercury may do good for a time that it cannot be given over a prolonged period without damage.

Foucar and Stokes[3] have reviewed the literature up to 1921 on the influence of arsphenamin and neoarsphenamin in the anemias associated with syphilis with the result that of nine clinical investigators six reported favorable results, one was opposed to treatment and two undecided or gave qualified opinions. Among investigators of the laboratory aspects of the problem of the influence of arsphenamin on the blood, five were in favor of the drug as a means of producing a rise in hemoglobin and erythrocytes and seven were against or gave qualified opinion. The general opinion appears to be that arsphenamin produces a transient destruction of erythrocytes followed by a rise of varying degree and permanence.

Foucar and Stokes have then reported upon the results of arsphenamin treatment of twenty-five cases of severe anemia associated with syphilis. Of these, thirteen cases presented the blood picture of pernicious anemia and twelve of severe secondary anemia. Five of the 13 patients with pernicious-like anemia improved under arsphenamin and 3 of these did not have demonstrable syphilis; 5 other cases became worse under arsphenamin and 2 of these had syphilis; of the 12 cases of secondary anemia, 5 improved under arsphenamin treatment, while, curiously, 5 with demonstrable evidences of syphilis, did not improve; 1 became worse. Mercury by inunction, used alone, produced an unfavorable reaction in 4 or 9 patients with anemias who had previously improved under arsphenamin, but all had primary anemia and subsequently showed evidences of a relapsing unfavorable course. Foucar and Stokes state, therefore, that in syphilis with anemia, mercury should be used with caution and especially if the picture suggests primary anemia of the pernicious type.

My experience has indicated that this complicated subject may be summarized somewhat as follows:

(1) The anemia of acute early syphilis is usually of the simple variety but may be progressive and quite severe during the first six months, when specific treatment has not been given. I have never seen the blood picture of pernicious anemia in these early cases but the so called chronic secondary anemia, which may develop in chronic syphilis, may present the blood changes of pernicious anemia and the true pernicious or specific cryptogenic hemolytic anemia may develop as a superimposed or independent disease.

Under treatment with arsphenamin, neoarsphenamin, sulpharsphenamin or mercury, the simple secondary anemia of early syphilis gradually improves; this is due to the destruction of *Sp. pallida*, the influence of arsenic upon oxidation and metabolism and possibly to a slight stimulation of erythroblastic tissues.

(2) The anemia of chronic syphilis is usually of the chlorotic type in which the hemoglobin is reduced out of proportion to erythrocytes. As a general rule, the blood improves under specific medication and especially when arsphenamin, neoarsphenamin, sulpharsphenamin or tryparsamid are administered; this is likewise ascribed to the destruction of *Sp. pallida*, but in larger degree to the influence of arsenic upon the retardation of oxidation and other metabolic changes.

(3) A chloro-anemia in chronic syphilis may be due to chronic tuberculosis, non-syphilitic nephritis, etc., or be a type of "constitutional anemia," which the patient has had almost as long as he or she can remember and certainly before syphilitic infection; this type of anemia usually improves under arsenical therapy but is subject to "ups and downs."

(4) The anemia of excessive mercurial treatment may be of the simple or chorotic type and improves very slowly spontaneously as mercury is eliminated; the arsenicals, however, tend to hasten restoration of the blood with a marked improvement in the general condition of the patient.

(5) Pernicious anemia as a *result of syphilis* is very rare. Foucar and Stokes state that apparently non-syphilitic cases of pernicious anemia may yield falsely positive Wassermann reactions, but my experience with 8 cases of pernicious anemia tested during the past four years by my new complement-fixation test, does not confirm this impression; in my opinion, pernicious anemia in the absence of syphilis does not give a positive complement-fixation reaction. It may be that syphilis alone can produce pernicious anemia; I have never seen a case in which this conclusion was warranted and doubt that such occurs. I have, however, seen several very severe anemias due to syphilis, presenting several of the blood changes of pernicious anemia including an increase of urobilin in the urine and feces. Doubtless, however, pernicious anemia may develop as a superimposed disease in syphilitics. While thorough treatment of the syphilis is indicated, yet the pernicious anemia is not likely to be cured by antisyphilitic treatment alone; as stated by Foucar and Stokes, blood transfusion should be a preliminary to arsphenamin when the hemoglobin is below 20 per cent. and reactions to arsphenamin injections must be carefully avoided since they may produce an alarming drop in hemoglobin.

Arsphenamin and Its Substitutes in the Treatment of Non-syphilitic Chloro-anemia.—In the chloro-anemias of chronic tuberculosis, furunculosis and other infections, intravenous injections of 0.1 to 0.2 gm. neoarsphenamin once a week for a series of injections, has sometimes yielded encouraging results in the way of an improvement in appetite, weight and slight progressive increases of hemoglobin and erythrocytes. Kall[4] and others have reported results of this kind and my experience has been that the results are usually as good as secured by subcutaneous injections of iron and arsenic without the disagreeable reactions sometimes accompanying the latter. Evidently these effects are mostly due to the influence of arsenic upon reduction of oxidation and metabolism rather than to any stimulation of the erythroblastic tissues or increased resistance of the erythrocytes to bacterial or other hemolytic agents.

But arsphenamin and its substitutes cannot be regarded as curative agents in a strict sense for the non-syphilitic chloro-anemias. These blood dyscrasias have a variety of causes and our chief efforts should be directed toward the detection and removal of these; when, however, it is believed that the administration of arsenic may hasten recovery I have no hesitation in recommending intravenous injections of small doses of neoarsphenamin (0.1 to 0.3 gm.) as a means for administering arsenic in an agreeable manner and in a form calculated to yield very much quicker and better results than follows the administration of inorganic arsenic by mouth. My usual plan in cases of this kind is to administer an injection once a week for six to ten weeks in succession while iron and strychnin are being administered daily by ingestion; the correction of constipation, which is usually present, receives particular emphasis, as likewise the correction of dietary and hygienic errors so commonly present.

Arsphenamin and Its Substitutes in the Treatment of Pernicious Anemia.—Naturally most interest has been placed in the treatment of pernicious anemia with arsphenamin and neoarsphenamin, owing to the fatal character of the disease. The etiology is still unknown but considerable data indicates that it may be due to an infection, probably not to a specific organism, but to a streptococcus or similar bacterial focal infection increasing erythrocytic destruction or hemolysis rather than retarding erythrocyte production, although asplastic changes in the bone marrow may be a terminal change. Hunter has particularly emphasized the importance of increased hemolysis

and especially in the portal distribution, as the primary change in pernicious anemia as indicated by the icteroid color of the patient, the distinctly yellow color of the plasma, polychromasia, fragmentation, shadowing and punctate granulation of the erythrocytes, as well as by enlargement of the spleen and the increase of urobilin in the urine and feces. It is not always possible to discover evidences of hemolysis, but the red, swollen and painful tongue, achlorhydria and progressive degeneration of the spinal cord along with the blood changes, are generally sufficient for diagnosis.

As stated above, it would appear that *Sp. pallida* may rarely produce a severe secondary anemia resembling the disease; at least, Leede,[5] Eason[6] and others have reported surprisingly good results from arsphenamin in cases of syphilis presenting the blood picture of pernicious anemia. But Winterfeld[7] has recently stated that there is no relation at all between syphilis and pernicious anemia, and when the two diseases co-exist, great care is required in treatment since arsphenamin may aggravate the anemia; in his opinion the anemia requires first consideration and by means of blood transfusion, with or without splenectomy, an effort should be first made to correct or improve it before the treatment of syphilis is undertaken.

As previously stated, Bramwell, in 1913 reported some success in the treatment of twelve cases of pernicious anemia with arsphenamin and since then Leede,[8] Steyser,[10] Boggs,[11] Lampe,[12] Lowrey,[13] Hobhouse[14] and numerous others have reported cases of the disease in non-syphilitic individuals benefited by the administration of arsphenamin and neoarsphenamin. To the best of my knowledge no cures have been attained but the compounds have appeared to favor the production of relapses of varying duration, which is about the best we can expect at present in the treatment of this dreaded disease. Similar results have also been observed with ascending doses of Fowler's solution by mouth pushed almost to the point of maximum toleration, as likewise with subcutaneous injections of sodium cacodylate. Iron, which may be so useful in the chloro-anemias, is of but slight or no value in this disease.

Just how the organic and inorganic arsenicals act in pernicious anemia is not known, but in those cases presumably caused by focal infections with hemolytic streptococci, I am inclined to believe that arsphenamin and neoarsphenamin may be of aid as direct bactericidal agents as discussed in Chapter VII, or indirectly, by stimulating leukocytosis and other non-specific bactericidal agencies. Possibly the arsenicals may stimulate the erythroblastic tissues, but they are evidently inferior to blood transfusions in this respect. Possibly they aid by reducing oxidation and otherwise improving metabolism and nutrition; in my experience they have not increased the resistance of the patient's corpuscles to hypotonic saline, saponin or serum hemolysins. But whatever the mechanism may be, these compounds are not able to cure the disease; whenever relapses of such long duration result as to amount to a clinical cure there is the suspicion of latent syphilis as the etiological factor.

When it is decided to use an organic arsenical in treatment, I believe that preference should be given to neoarsphenamin or sulpharsphenamin rather than to arsphenamin, because of the necessity for avoiding toxic reactions. I have not employed tryparsamid and do not know how it compares with the other two arsenicals in this regard.

My plan is to give a series of intravenous injections of neoarsphenamin in dose of 0.2 to 0.4 gm. dissolved in 10 c.c. of sterile water (solution is not hemolytic) at intervals of one to two weeks. When small transfusions of citrated blood are being given, it is permissible to add the neoarsphenamin

to the blood and inject both together. In my experience best results have followed a series of small transfusions (150 to 200 c.c.) of blood at intervals of one to two weeks along with intravenous injections of neoarsphenamin with the blood or by separate injections within a day or two after each transfusion. Some physicians are opposed to transfusions when evidences of hemolytic activity are present, but I believe in them at this stage of the disease, extraordinary care being taken, however, in the selection of donors to avoid reactions as far as possible and preference being given to direct methods of transfusion to avoid toxic citrate reactions. Weekly or bi-weekly examinations of the blood are made and the treatments stopped when the blood is progressively improving. These are followed, however, by occasional intramuscular injections of 0.2 to 0.3 gm. of sulpharsphenamin dissolved in 2 to 3 c.c. of sterile water, to continue the arsenical effects; also by the administration of Fowler's solution by mouth. Needless to state, a very careful search is made for foci of infection; when accessible, cultures are made and autogenous vaccines prepared and administered along with measures for the correction of other factors if present, as hypo-acidity of the gastric juice, constipation, dietary and hygienic errors. I have no opinion to offer upon the value of splenectomy; in two cases, however, presenting active signs of hemolysis, I have seen splenectomy apparently followed by prompt relapses lasting respectively eight months and a little over two years; in a third case, splenectomy was followed by progressive and rapid impoverishment of the blood and spinal cord degeneration with death about three months later. On the whole, however, I believe that splenectomy is indicated when the spleen is considerably enlarged and when the blood picture and urobilin tests show progressive hemolysis uncontrolled or checked by arsenic and blood transfusions.

Germanium Dioxid and Sodium Germanate in the Treatment of the Anemias. Within the past few years, considerable interest has been aroused in the possible value of germanium dioxid, and especially sodium germanate, in the treatment of pernicious and other anemias.

The existence of germanium, its atomic weight and chemical properties being foretold by Mendeleeff[15] in 1871 by the aid of the periodic law, it was not discovered until fifteen years later by Winkler[16] in the silver ore argyrodite at Freiberg, Germany. In 1922, Muller, having isolated a small amount of germanium in the Harrison Chemical Laboratories of the University of Pennsylvania, was interested in the matter of its toxicity as compared with arsenic, and in a study of this kind, Hammett, Muller and Nowrey,[17] in comparing the relative toxicity of germanium dioxid and arsenic trioxid for the mature albino rat, found that the former could be given subcutaneously in doses up to 0.180 gm. per kilo of body weight with no apparent toxic effects, but that the latter generally proved fatal in doses of 0.008 gm. per kilo of body weight.

A study of the blood by the same investigators[18] following subcutaneous injections, revealed a marked and sustained rise in the number of erythrocytes, the increase ranging from 1 million to 5 million erythrocytes per c.mm. This increase occurred, as a rule, within a week's time and after one or two injections. A greater response was always noted in those test animals with low initial counts and *vice versa*, thus suggesting a relationship between the degree of response and the original number of red blood cells present. In comparing the degree of response with the size of the dose, no evidence was obtained to show that the larger doses exhibited a greater stimulating effect than did the smaller ones. Histologic examinations of the bone marrow of the germanium-treated rats gave evidence of a marked increase of nucleated erythrocytes over the number present in the marrow sections of the controls. The circulating blood of the test animals likewise exhibited a greater number of young red cells than the blood of the control animals. No changes were noted in the white blood cells. Muller and Iszard[19] demonstrated a similar erythrocythemia following administration of germanium dioxid in the guinea-pig, rabbit, dog, and man. In the case of man, the dose was administered orally, and apparently absorption occurred very promptly when given in this manner. Germanium dioxid was found not to accumulate in the system, but readily eliminated through the kidneys and in small part through the alimentary tract. The lethal dose as calculated by Muller and Iszard was about 0.586 gm. per kilo of body

weight. In my toxicity tests employing white rats of 100 to 150 grams injected intravenously with a solution of germanium dioxid furnished by Dr. Muller, the maximum tolerated dose was found to be slightly higher than 0.510 gm. per kilogram. Tests for trypanocidal activity employed rats infected with *Tr. equiperdum* and treated with intravenous injections as described in Chapter X, according to the technic of my method, showed that doses as high as 0.510 gm. per kilo restrained trypanosome infections for a day or two, but were unable to sterilize the animals; spirocheticidal tests employing rabbits with acute testicular syphilitic lesions and treated intravenously with germanium dioxid, were without effect. It would appear, therefore, that the toxicity of this substance is very low, but that it is also practically devoid of trypanosomal, spirocheticidal and bactericidal properties.

Hammett and Nowrey were the first to report upon the administration of germanium dioxid in the treatment of various anemias; Leukins[21] and Schmitz[22] have reported favorable results but Alexander,[23] Stengel,[24] Garvin[25] and others have reported that germanium dioxid produced practically no increase of erythrocytes or hemoglobin. Nowrey,[26] working with normal rats, likewise found that injections of germanium dioxid in neutral solution showed little or no change in the erythrocyte counts and hemoglobin estimations, but that a solution of sodium germanate produced a marked increase in erythrocytes and hemoglobin.

The exact status and value of germanium in the treatment of the anemias cannot be stated, but it would appear that sterilized solutions of sodium germanate (pH 7.4) are to be preferred to germanium dioxid and may prove worthy of trial in dose of 0.025 to 0.050 gm. by subcutaneous injection for an adult of average weight or 0.010 to 0.025 gm. by intravenous injection. By oral administration much larger doses (0.250 gm.) are required, which greatly increases the expense involved in the treatment. It would appear that the results have been much better in secondary anemias than in pernicious anemia, but this is to be expected and it is doubtful if germanium is superior to arsenic in these cases. It is practically certain that germanium has not fulfilled the hopes and expectations originally expressed in the treatment of pernicious anemia; but it is not reasonable to expect success in this disease until more is known of the nature of the hemolytic agents and processes concerned.

Chemotherapy of Malignant Tumors.—Owing to the high incidence and mortality of malignant tumors it is not surprising that early and persistent attempts have been made to unravel the mystery of their cause and to develop empirically an efficient means for specific treatment.

The ease with which certain cancers and sarcomas of the lower animals are transmissible through an indefinite number of generations along with certain manifestations of natural and acquired immunity, has greatly stimulated efforts towards the discovery of a parasitic cause and numerous organisms have been described in this connection. Space does not permit me to review in detail the large amount of investigation devoted to the etiology of malignancy but the results would appear to warrant the following deductions of direct interest in relation to chemotherapy.

Malignant tumors of human beings and the lower animals have been produced by prolonged irritation and notably by certain tars, paraffin and soot. It is possible that chemical agents of these kinds produce fundamental changes in the cells enabling them finally to produce continuously and of their own accord, growth-stimulating substances which normal tissues elaborate only in response to cell damage, that is, in malignancy the cells acquire the property of producing continuously and in relatively large amounts the same sort of stimulating substance that adult tissues produce or release when injured, for exciting reparative processes. The converse of this mechanism however, is also a possibility, namely, that prolonged irritation

results in the cells producing substances capable of neutralizing physiological restraint upon cellular proliferation and activity. Since, however, chemical irritants of these kinds may be concerned in only a fraction of malignant growths of human beings, other irritants must be thought of and it is possible that a specific parasite or any one of a number of non specific organisms may produce toxic agents capable of acting as the same kind of irritant and bringing about this fundamental and transmissible change in cells resulting in the continuous production of a cell stimulating substance responsible for their rapid and riotous proliferation. On the other hand malignancy may be due to a combination of factors of these kinds as recently stated by Gye and Barnard,[27] namely, that malignancy is caused by a specific virus but that it is ineffective until a second substance, obtained from tumor cells, breaks down the cell defenses and enables the virus to infect. This second substance in turn may be a product of the cells from the effects of prolonged irritation. The experiments upon which this hypothesis is based were conducted largely with the Roux chicken sarcoma. But Harkins, Schamberg and myself[27a] have not been able to confirm this work. In our experiments when sufficient chloroform was added to the tumor emulsion to kill the virus in the preparation of "specific factor," we were unable to produce tumors by injecting it along with subcultures of the primary tumor culture. In other words we believe that the so called "specific factor" of Gye is an attenuated but living virus of the tumor, rather than a chemical substance from the cells.

How may chemotherapy influence such processes? If malignancy is due to a specific virus alone it may be possible to discover a specific destructive chemical agent for it and this would be the simplest possibility of all. If malignancy is not due to a specific organism but rather to a fundamental change in cells as a result of prolonged irritation, an effective chemotherapy would be called upon to destroy the cells producing the growth stimulating or activating substances. If the irritant producing these changes were purely of a chemical nature like tar or paraffin, chemotherapy could do nothing in removing it but if the irritant were being produced by a specific or non specific organism, an effective chemotherapy would be expected to serve a dual function, namely, the destruction of the organism producing the irritant and secondly, the destruction of the cells already changed by the irritant to produce the cell stimulating substance.

But before passing in brief review the results of a large amount of investigation in this field, it may be well first to clearly establish in our minds what should be the criteria by which they are to be judged. This is all the more important, since as so well expressed by Weil,[28] "the natural course of the disease is associated with such fluctuations that a sanguine therapeutist can gain some encouragement from even the most hopeless cases. Hence it follows that every mode of treatment has found adherents. The market is flooded with cancer drugs, and cancer charlatans flourish in the most highly educated communities. Unfortunately even well-trained, honest and reputable physicians have fallen victims of this fallacy, and have lent their names to the support of modes of treatment which in reality produce no determinable effect on the natural evolution of the disease." It was the desire to combat this unfortunate tendency which led Weil[29] to attempt to establish the criteria of therapeutic effects in cancer, which were summarized with the statement that the *demonstrable reduction in size of a tumor, of a kind not to be attributed to the natural processes of evolution of that tumor or of its associated lesions, is the one essential feature of effective therapeutic intervention.* To this I would add that the effects must be of a permanent character and influence

favorably not only the primary growth but the metastatic lesions as well. Furthermore, that the effects should be lasting and recurrences prevented since it is apparently so easy to produce such temporary effects as reduction of pain, cessation of discharge and the healing over of carcinomatous ulcers by the administration of various tissue extracts and serums producing non specific protein reactions oftentimes of temporary benefit to the patient and readily enough interpreted as specific results by both the patient and physician.

In other words, so many substances like various so-called specific sera, vaccines of cancer cells, tissue and other autolysates, etc., which I have listed elsewhere,[30] may temporarily influence the associated symptoms of malignant tumors and in exceptional cases even bring about temporary or permanent regressions, that great care is required in accepting any of them as truly curative of the disease. It is not surprising that colloidal shock reactions elicited by protein agents or the heavy metals may produce inflammatory reactions about the tumors with improvement in pain or hemorrhage, but these alone are not to be accepted as criteria of cure.

With these criteria clearly in mind we may now briefly review the results of chemotherapeutic investigations in malignant tumors of the lower animals and human beings. No one has seriously questioned the true malignant nature of the experimental cancers and sarcomas of the lower animals and if anything were discovered truly curative for their metastases in the internal organs, great hopes could be entertained for similar effects in the malignant tumors of human beings, although softening of the subcutaneous tumors alone would be of much less significance. Of course all such studies have been purely on the "hit or miss" fashion since the etiology of malignancy is still unsolved, but I believe it may be stated that most investigators have worked with the idea in mind that the cancer cell itself is the primary object for destruction rather than a hypothetical parasitic agent. This of course would require of a chemical agent an extreme degree of specific affinity for these cells in order to spare the normal cells, which they so closely resemble.

It may be here stated however, that a substance unable to favorably influence an adeno-carcinoma of the mouse or a sarcoma of the rat, may not be necessarily without effect upon cancer of the human being; there is in other words a limitation to the value of animal experiments. The experimental disease runs a very much more acute course than malignant disease in human beings which may readily enough mask therapeutic effects, just as a severe experimentally produced bacterial infection may mask the therapeutic effects of an anti-serum or chemotherapeutic agent. I believe therefore, that animal tests have a greater positive than negative value and if anything is discovered truly curative for a mouse cancer, great hopes could be entertained for it in the treatment of cancer of human beings.

Probably the first scientific investigation was undertaken by Wassermann and Keysser[31] in 1911 in the treatment of cancers of mice with selenium-eosin compounds, the idea being that selenium may prove selectively destructive for cancer cells when brought to them by the eosin. Some cures were claimed and the report attracted a great deal of attention, but few details were given, the promised follow-up report was not made, Keysser[32] later reported that by far the larger proportion of animals died during treatment in the stage of softening and Uhlenhuth,[33] Contanim[34] and others were unable to confirm the findings. In truth the softening of the subcutaneous tumors was probably caused by trauma from excessive handling and squeezing of the growths; at least it was shown by Keysser[35] himself that selenio-vanadium compounds were without influence upon the metastatic growths in the internal organs.

It had been pointed out by Carl Lewin[36] that the therapeutic results obtained from subcutaneous mouse tumors, however encouraging, could not be logically applied to the treatment of human cancers. The subcutaneous transplanted tumors, as is well known, are as a rule limited by a distinct capsule and show no tendency to infiltrative growth. In this particular they present a most striking difference when compared with human tumors. On the other hand, the metastases of mouse tumors in the internal organs present an infiltrative mode of growth and thus approximate very much more closely to the human type of tumors. Keysser, therefore, determined to test the therapeutic effectiveness of his compounds on tumors implanted in various organs, but the results with carcinoma, adeno-carcinoma and sarcoma were regularly and consistently negative. Furthermore, it was shown that mixtures of eosin-selenium-vanadium and a suspension of mouse tumor cells *in vitro* did not result in the destruction of the latter, as shown by production of tumors when injected into mice.

In the meantime Neuberg and Caspari[37] thought that complex organic compounds of the heavy metals like zinc, platinum, tin, selenium, copper, silver and cobald may exert a favorable influence upon malignant mouse tumors by undergoing a transformation in the tumors to colloid substances which in turn brought about a destruction of tumor cells by increasing autolysis by ferments. For the latter assumption there is absolutely no evidence; it is due simply to the influence of the colloidal theory. If one critically examines the data on which this theory is based, one is forced to the conclusion that it has practically no established claim to validity. If we grant that colloidal metals have been shown to stimulate autolysis in the test tube, the same fact must be admitted of metals in non-colloidal solution. Izar[38] thought that he cured some rat tumors by injections of colloidal sulphur; Lewin made a similar claim for various preparations of gold in mouse tumors and Werner and Szecsi[39] produced similar results with a combination of selenium-vanadium with cholin-borate.

Keysser carried out experiments along the lines inaugurated by Newberg, using a combination of glycocoll and copper. He also tested the combination of borcholin with selenium-vanadium used by Werner and Szecsi. He was able to confirm the fact that both of these substances produced an unmistakable therapeutic effect on subcutaneous tumors. On the other hand, they were absolutely without influence on the internal tumors. In this respect, therefore, they were entirely comparable with the eosin-selenium compound. The thoretical basis constructed by Newberg, which rests on the assumption that the metallic compounds stimulate autolytic processes in the tumors, was also subjected by Keysser to destructive criticism. Finally, Keysser showed that none of these therapeutic agents were effective even in the case of subcutaneous tumors, unless the latter had reached at least the size of cherry pits. If a therapeutic injection were made immediately after inoculation of the tumors, no effect was observed. The tumors grew exactly as in the controls, and the animals died in about the same period of time.

It is quite clearly established therefore, that none of the preparations of which the therapeutic effectiveness has hitherto been proclaimed exercise any direct influence on the life or development of malignant tumors of the lower animals. Under certain very definite and restricted conditions, however, they may produce certain changes in the tumors, and in a small proportion even cures. These results, however, were obtained only in the case of tumors which were subcutaneous in location, not smaller than a cherry pit in size and probably caused by constant palpation and examination of the subcutaneous tumors resulting in circulatory changes with hyperemia and hemorrhage.

These circulatory changes in turn may be responsible for the increased tendency of the injected substances to lodge in the tumors, thereby possibly increasing the tendency to autolysis which the circulatory changes have inaugurated. It is, of course, questionable whether this explanation can be regarded as final but enough has been done to show that the iodids and various dyes, injected intravenously, tend to accumulate to a greater extent in the necrotic portions of subcutaneous and internal tumors of mice and human beings, than in other tissues. These in turn may increase autolysis and thus explain the results observed up to the present time on a purely non-specific basis and without involving the questions of specific destructive affinity between chemical agents on one hand and cancer cells and hypothetical cancer virus on the other.

Of course clinicians were not slow in utilizing these observations for the treatment of human cancers and the various types of preparation employed may be satisfactorily grouped under four classes as follows: (1) The crystalline salts of selenium; (2) selenium in colloidal solution; (3) other metals in colloidal solution; and (4) compounds of metals with organic radicals.

These substances have been administered by injection or by the mouth. Before passing to a further consideration of this subject however, it may be well to recall the fact that in the experimental tumors of animals, no matter what preparation has been used, it has been possible to accomplish therapeutic effects only by the use of relatively enormous doses of the medicament; of doses, in fact, which were scarcely lower than the lethal doses. Certain experimenters have noted that smaller doses actually stimulated the growth of the tumors. In the second place, it has almost invariably been found necessary to administer the treatment intravenously, inasmuch as the other modes of administration failed of therapeutic effect. It is quite apparent therefore, that a procedure in human beings in any degree analogous to that pursued in animals may be dangerous or impossible.

The majority of those who have worked with selenium have used it in colloidal form, either preparing it themselves or employing one of the preparations put on the market by the pharmaceutical firms. The results obtained are fairly concordant. The intravenous injection of these preparations produced but slight disturbances. There was leukocytosis, a moderate rise of temperature, and not infrequently a chill. Otherwise, the substances seemed to possess no toxicity. The effects produced on the tumors have almost invariably been reported as encouraging while some have observed nothing from selenium other than the temporary improvement which is shown by almost all cancer cases on the application of any new therapeutic measure.

Colloidal silver and colloidal copper have likewise been tried with generally negative results. McClurg, Sweek, Lyon, Fleisher and Loeb[41] however, have observed that intravenous injections of cancerous mice with colloidal copper and casein compounds sometimes produced a primary inflammatory change about the tumors followed by a secondary reaction leading to a diminution in size of the tumors by shrinking of the tumor and in some instances to a healing over of carcinomatous ulcers.

Of course arsphenamin and neoarsphenamin have also been tried but with entirely negative results in the experimental tumors of rats and mice; a few human beings have been reported as cured but it is highly probable that the lesions were syphilitic rather than malignant.

In this brief survey I have not attempted to cover the enormous literature upon the subject and especially that relating to the treatment of malignant disease of human beings. Suffice to state that for almost every preparation

described as beneficial in experimental tumors of mice and rats the claim has been made, practically without exception, that it exercises a markedly beneficial effect on malignant disease in the human being. How are we to interpret these observations? How are we to explain the fact that they are the invariable accompaniment of the most diverse methods of treatment? As stated by Weil, when the various methods of treatment which have been discussed are judged by the criteria given above, "it is apparent that none of them can lay claim to therapeutic effectiveness. The modifications of the disease attributed to them are modifications which occur spontaneously in a very large proportion of cases as a result of the natural evolution of the disease process. This is a fact which cannot be too strongly emphasized. Owing unfortunately to the hopeless character of cancer, men are not prone to study with care all the lesser changes which the disease and the patient present under ordinary conditions; but when a cure is under investigation, the patient and his medical attendant note every apparent improvement with painstaking attention and enthusiasm. As a result, some evidence of improvement in treatment is entered on the books." I believe that the subject however, is worthy of further efforts and especially if it is finally shown that cancer is due to a specific organism or organisms; in the meantime a search for chemical agents capable of merely arresting the active proliferation of tumor cells is worth while.

In this connection most attention is being attracted at the present time by the intravenous injection of lead in colloidal suspension by Bell and his associates[41a]. Bell has observed the frequency of abortions among lead workers due to coagulation necrosis of the chorionic epithelium and on the basis of the theory that cancer is a reversion on the part of starving cells to the nutriment seeking proclivities of their ancestral types, the chorionic epithelium, various preparations of lead, copper, thallium and thorium have been tried in the treatment of hopeless cases of cancer in human beings. Some rather remarkable results have been observed at present following intravenous injections of a colloidal suspension of lead prepared by the "sparking process," and stabilized with small amounts of gelatin and calcium chlorid. The amounts injected however, have been near the lethal doses and the patients kept on the verge of lead poisoning. It is stated that improvement and apparent cures have followed in some cases and especially in cancers of vascular tissues when the injections have been used jointly with roentgen ray and surgical treatment. At this writing however, the full details of preparation of the lead and dosage have not been disclosed and it is too early to express a definite opinion of this method of treatment.

Chemotherapy of Rabies.—The uniformly fatal nature of rabies in the lower animals and human beings has led to a number of attempts to develop a chemotherapy for this dreaded disease but with almost entirely negative results.

In 1908, Friedberger and Sachs[42] tried thioglycollic acid and atoxyl by subcutaneous injection in the treatment of seventeen rabbits, experimentally infected, during the incubation period; in one the incubation period was slightly prolonged and in another symptoms did not develop. Intravenous injections of arsenophenylglycin apparently cured one rabbit, but these results were probably due to some fortuitous circumstances, since they could not be duplicated; indeed, arsenophenylglycin in dilutions 1:10 to 1:1,000,000 with the virus *in vitro* was found unable to kill the unknown germ as determined by subdural injections of a portion of each mixture into rabbits.

Naturally, after the discovery of salvarsan (arsphenamin), this compound was employed; but the reports of Marras,[43] v. Lumbusch,[44] Mijia,[45] Wesson and others have shown that intravenous injections of arsphenamin and neoarsphenamin, even in massive doses, have had no effect upon either experimental rabies of dogs, rabbits and guinea-pigs or upon the disease of human beings.

The only really encouraging results observed up to the present time were reported by Moon[46] in 1913 who found that three dogs experimentally infected with street virus and treated with large doses of quinin by mouth survived, while the controls succumbed. In a subsequent study, however, Moon[47] found that quinin by mouth and subcutaneous injection failed to be regularly effective as a cure or preventive of rabies in animals. Given in the later stages of the disease in two human beings, it was likewise ineffective. Moon believes, however, that quinin may retard the development of street rabies if given in the incubation period and that the organism is somewhat influenced, thereby opening up a "lead" for the development of chemotherapy for this disease. Frothingham and Halliday[48] and Krumniede and Mann,[49] however, have reported almost entirely negative results.

My associate, Dr. Malcolm J. Harkins, has recently repeated this work[50] with rabbits experimentally infected by subdural injections of fixed virus. Treatment was begun four hours after infection and continued throughout the period of incubation until symptoms developed. Quinin bisulphat and ethylhydrocuprein hydrochlorid, given in dose of 0.005 gm. per kilogram by daily intravenous injection, were without appreciable effects. Neoarsphenamin and sulpharsphenamin, given intravenously in the large dose of 0.15 gm. per kilogram four hours after infection and then every three days for a total of three doses, were without effect. Gentian-violet in dose of 0.010 gm. and mercurochrome in dose of 0.005 gm. per kilogram, by intravenous injection within twenty-four hours after infection followed by repeated injections at intervals of three days, were also without effect. Potassium tartrobismuthate, in dose of 0.05 to 0.125 gm. per kilogram by intramuscular injection, starting two hours after infection and repeated daily, was likewise without effect. Additional experiments were conducted by mixing 0.2 c.c. of an emulsion of rabies virus (fixed) with 0.2 c.c. of a 1:100 solution of neoarsphenamin; duplicate mixtures were prepared with 1:100 sulpharsphenamin, 1:250 flumerin, 1:500 flumerin, 1:500 mercurophen and saline solution (control). After keeping the mixtures in a water-bath at 38°C. for thirty minutes, rabbits were injected intracerebrally with 0.2 c.c. of each mixture; all developed rabies in six to seven days, showing that these compounds were without effect. These results are especially striking in view of the very high bactericidal activity of the mercurials (mercurophen and flumerin) and suggest to me that the germ of rabies must be well protected by location in large brain cells effectively resisting penetration by these substances.

Nothing of value, therefore, has been discovered for the treatment of rabies, and immunization with vaccine continues to be the best prophylactic measure. It is to be hoped, however, that efforts toward the development of an efficient chemotherapy will be continued, and especially since it is so easy to conduct laboratory experiments in rabies with dogs, rabbits or guinea-pigs. In this connection, I may also mention that Dr. Harkins has succeeded in producing the disease in white rats by intracerebral injections of 0.1 c.c. of emulsion of virus; the animals developed the dumb variety of the disease on or about the sixth day and succumbed on the seventh.

Arsphenamin and Neoarsphenamin in the Treatment of Chorea.—Milian[51] has particularly advocated the treatment of this disease with arsphenamin and neoarsphenamin, believing that a large proportion of cases are due to congenital syphilis, but in a recent thorough study of a series of cases along with an extensive review of the literature, Morse and Floyd[52] arrived at the conclusion that, while syphilis may be occasionally found in cases of chorea, it bore no essential etiological relationship to the disease. Their study included very careful blood cultures, blood Wassermann reactions and examinations of the spinal fluid, and they believe that the results show an intimate relationship between chorea, rheumatism and endocarditis indicating that chorea is probably caused by a group of organisms apparently entering through the tonsils or some other focus of infection. While neoarsphenamin, arsphenamin or sulpharsphenamin may be worthy of trial and especially since arsenic is of known benefit in many cases of the disease, it cannot be stated that these compounds possess specific curative properties.

Arsphenamin in the Treatment of Pemphigus, Pellagra, Warts, Herpes Zoster, Verruga Peruviana, Sprue and Small Pox.—Owing to the highly fatal character of *pemphigus* (vulgaris and foliaceus), it is not surprising that numerous and early attempts in treatment were made with intravenous injections of arsphenamin by Sutton,[53] Eschweiler,[54] Merz,[55] Stumpke,[56]

Frieboes,[57] Wolfe[58] and others. In some instances beneficial results were claimed, but it is possible that these were confused with the temporary remissions of the disease or that mistakes in diagnosis were made. I have not myself seen any benefit from intravenous injections of neoarsphenamin, except such slight improvement as may be expected from the effects of the drug on metabolism. I am convinced that the organic arsenicals do not possess a specific action in pemphigus, which, according to recent investigations of Eberson, may be a bacterial infection. My colleagues Greenbaum and Schamberg, have noted temporary improvement following intravenous injections of mercurochrome.

Siemens[59] has recently reported upon the treatment of 34 cases of *warts* by injecting into them 0.15 c.c. of 1:15 to 1:40 dilutions of arsphenamin in saline solution. The injections produced slight pain in most cases, but is reported to have cured a number in from ten days to four months. The results are interesting in view of the work of Wile and his colleagues, showing that warts are caused by a filterable virus; also, in view of the successful results reported in the treatment of *verruca plana* with arsenic. Lindsay[60] believes that there are many cases of warts which the intravenous injection of neoarsphenamin is justifiable, in the hope of accomplishing by intensive arsenical treatment what may not be possible with milder forms of arsenic.

Since various types of *herpes*, including herpes zoster, are now known to be caused by a filterable virus, the subject of chemotherapy in this disease becomes one of considerable interest and especially in view of the ease by which lesions may be produced experimentally on the corneæ of rabbits, guinea-pigs and white rats. Grebb[61] has reported the apparently successful treatment of 2 cases of herpes zoster with arsphenamin, but it may be that these effects were due to natural remissions. I have not myself observed any curative effects in herpes zoster to be ascribed to neoarsphenamin administered by intravenous injection.

With the assistance of Dr. Harkins, I have produced experimental herpetic infections of the brains of rabbits and the following compounds were injected intravenously within four hours after inoculation and repeated every two days in these doses per kilogram of weight: arsphenamin, 0.010 gm.; neoarsphenamin, 0.015 gm.; mercurochrome, 0.003 gm.; gentian-violet, 0.005 gm.; quinin bisulphat, 0.005 gm. and ethylhydrocuprein hydrochlorid, 0.005 gm. Untreated controls were included, but none of these compounds appeared to retard the disease beyond the usual variations shown by the controls; neither were curative effects elicited by the treatment of rabbits with lesions fully developed.

The etiology of *verruga peruviana* is still unknown, but many features of the disease indicate that it may be caused by a parasitic protozoon. Hypodermic injections of arsenic have been recommended and Castellani states that arsphenamin and neoarsphenamin are worthy of trial, but I do not know of any case reports showing that these compounds possess curative activity.

The etiology of *sprue* is still undecided, but evidence at present indicates that the *Monilia* described by Kohlbrugge may be the cause or at least an important secondary infection. Castellani and Low have described several species of *Monilias* which they believe may cause certain important symptoms, such as frothiness of the feces, but they are not inclined to consider these organisms as the primary cause of the malady. Smith,[62] however, has recently stated that experiments support Ashford's theory[63] of the specific etiology of sprue as due to *Monilia psilosis* by the production in guinea-pigs of a chronic moniliasis with gastro-intestinal lesions roughly comparable to

those found in man. The development of the lesions, however, was rarely noted except in animals fed on a diet partially deficient in vitamins, especially the antiscorbutic vitamins. This favors the view that a deficient diet, or diminished resistance, such as is common following long residence in the tropics, associated frequently with gastro-intestinal infections such as amebic dysentery, are contributory factors in its production.

Nothing in the form of specific chemotherapy has been developed for the disease, although it would appear that neoarsphenamin, emetin and tartar emetic may be worthy of trial on account of their general protozoicidal properties.

Arsphenamin has also been used by Lenzman[64] and others in the treatment of *small-pox* with apparently some benefit; also by Cranston[65] in the treatment of *pellagra*. But it is likely that the beneficial results reported have been due to the well-known general "tonic" effects of the arsenic rather than to specific parasiticidal action.

Chemotherapy of Contagious Pleuropneumonia, Equine Influenza, Foot and Mouth Disease, and Other Diseases of the Lower Animals.—Naturally many of the diseases of the lower animals of doubtful or unknown etiology have likewise been treated with arsphenamin, neoarsphenamin and other compounds, with the hope that good therapeutic results might be obtained, while at least no harm was being done. In several of these diseases really good and encouraging results have been reported and I shall here consider a few of them, with which I have some familiarity, although I am not equipped by experience to consider all the diseases of the lower animals in which chemotherapy has been tried with varying success. A very complete account of these, however, may be found in the treatise by Hutyra and Marek on the "Spezielle Pathologie und Therapie der Haustiere."[66]

The etiology of *contagious pleuro-pneumonia* of horses is still undecided, both *Streptococcus pyogenes equi* and *Bacillus (bipolaris) equisepticus* being regarded by some of the etiological agents. Arsphenamin and neoarsphenamin, however, have apparently yielded excellent results in treatment by intravenous injection. The dose of both is the same as for human beings, namely, 0.010 gm. of arsphenamin and 0.015 gm. of neoarsphenamin, per kilogram of weight. This amounts to about 3 gm. or arsphenamin and 4 gm. of neoarsphenamin for a large horse of ordinary weight and 2 gm. and 3 gm. respectively for smaller animals. Neoarsphenamin is probably to be preferred, because of lesser toxicity and greater ease of administration; 2 or 3 gm. are dissolved in 50 to 60 c.c. of sterile distilled water and injected slowly with a syringe. Arsphenamin is dissolved in at least 400 to 600 c.c. of sterile water and alkalinized, as described in Chapter LXII, before injection.

Practitioners are not agreed on the best time for injection, some stating that treatment should be given in the first day and others advising waiting to the fourth day, but the majority advise early treatment and not later than the third day after the onset of symptoms.

Toxic reactions may follow the administration of either drug and especially arsphenamin. In exceptional instances collapse has occurred with death of the animal, but in the great majority of cases the reaction disappears within four to six hours after injection with prompt amelioration of the fever and other symptoms of the disease.

Gordsjalkowsky,[67] in 1912, reported excellent success in the treatment of 35 cases occurring in a regiment of cavalry in Russia, with intravenous injections of 2 gm. of arsphenamin; one dose was ordinarily sufficient. Rummel has employed atoxyl but without success. Since then a very large literature

has accumulated on the subject and while it cannot be stated that neoarsphenamin is an absolute specific for the disease, it has been demonstrated that the drug produces a crisis, greatly shortens the duration and reduces the mortality from 5 to 20 per cent. to less than ½ per cent. During the World War both arsphenamin and, especially, neoarsphenamin, were used with great success and now that the costs of arsphenamin and neoarsphenamin have been greatly reduced, either compound may be more freely employed for the treatment of this dreaded disease and especially in epidemics among valuable animals.

Influenza of horses is regarded as an infection caused by an unknown filterable virus. Various drugs have been used with indifferent success, as 25 to 50 c.c. of 1:1000 methylene-blue mixed with the food and injections of atoxyl, arsenophenylglycin and other organic arsenical compounds. Arsphenamin and neoarsphenamin by intravenous injection, in dose of 0.010 to 0.015 gm. per kilogram respectively, appear, however, to have yielded very good results as reported by Gohre,[68] Stange and Szulewski,[69] v. Capelle[70] and others.

Foot and mouth disease, so prevalent and destructive among cattle in all parts of the world, is likewise believed to be caused by a filterable virus. Arsenophenylglycin, atoxyl and other pentavalent arsenicals have been employed in treatment without appreciable results, but arsphenamin and neoarsphenamin have apparently proven more efficacious in the way of shortening the course of the disease and reducing the mortality. Kroncke,[71] for example, has used intravenous injections of silver arsphenamin, starting with such a small dose as 0.1 gm. for an animal of average size. More than two injections were not required; the lesions were treated locally with chromic acid or calcium chlorid. Arsphenamin or neoarsphenamin may be used instead of silver arsphenamin and are apparently worth trying in the treatment of valuable animals, being given in dose of 0.010 gm. per kilogram or about 2 gm. for the average animal. Pullman[72] has recently stated that intravenous injections of trypaflavin are sometimes effective.

Darrow[73] has recently reported successful results in the treatment of *contagious lymphangitis* with neoarsphenamin.

Graybill[74] has tried ipecac in the treatment of *black-head* in turkeys, but with negative results.

PART VII

INFECTION, IMMUNITY AND PATHOLOGY OF SYPHILIS IN RELATION TO TREATMENT

CHAPTER XXXV

MECHANISM OF INFECTION WITH SPIROCHÆTA PALLIDA AND THE PATHOGENESIS OF SYPHILIS IN RELATION TO TREATMENT

The etiological agent of syphilis is now so universally accepted as the parasite discovered by Schaudinn in 1905 and named by him and Hoffmann[1] as *Spirochæta pallida*, that this subject does not here require discussion. A few months later Schaudinn for biological reasons renamed the organism as the *Spironema pallidum*, but this name not being permissible under the rules of zoological nomenclature, was again changed by him on October 26, 1905, to *Treponema pallidum*. Since then both terms have been employed.

Of considerable interest in this connection however, is the possibility of the spirochete of syphilis having been first seen and briefly described by Donne[1a] in 1837, in a study of the chemistry and cells of the vaginal secretions. Certainly he appears to have seen spiral-shaped organisms in the secretions of syphilitic ulcers of the female genitalia and in one case of leg ulcer, which he called "animalcules," and states were first described by Müller under the name "*vibrio lineola*." Of course he may have seen saprophytic spirochetes in the secretions of these parts but states that the vibrios were not found in non syphilitic women and a perusal of his little book leaves one with the impression that he actually saw the spirochete of syphilis, produced the disease experimentally by inoculations with it and was himself convinced that the organism bore an important relation to venereal infection and especially to the etiology of the chancre. Indeed his work was so thorough that one is surprised that this organism failed to excite more interest in relation to the etiology of syphilis.

At the present time *Spirochæta pallida* is regarded by some as a bacterium, by others as a protozoon and by a few as belonging to the domain of Protista, i.e., to neither the plant nor the animal kingdom. The subject is not without significance and importance in relation to the science of chemotherapy, but the majority of zoologists now appear to be convinced that the organism is a protozoon, i.e., belongs to the animal rather than the vegetable kingdom.

Terminology: Spirochæta pallida vs. Treponema pallidum.—Most German and English writers have used the name *Spirochæta pallida;* French authors commonly employ at present the terms treponemes and *Treponema pallidum*. In the United States both terms are employed, the former, however, more commonly than the latter. Pusey[2] states that the term *Spirochæta pallida* is to be preferred, since it is best known, mostly employed and

hardly worth while abandoning in favor of *Treponema pallidum* until the biological evidence in favor of the latter term becomes absolutely conclusive. Stiles[3] has summarized various reasons for the use of the term *Treponema pallidum*, but in view of the difficulties and lack of unanimity in the taxonomy of the subject, I decided to employ the term *Spirochæta pallida* throughout this book with the understanding that it is the same organism known as *Treponema pallidum*.

Possibility of a Granular Stage in the Life Cycle of Spirochæta Pallida.—The physical characters of *Spirochæta pallida* are likewise well known but from the standpoint of the prenatal or congenital transmission of syphilis the question, whether or not the spirochetes have a morphological stage other than the well-known spiral or cork screw shape becomes of considerable interest and importance. For example, clinical experience indicates that the paternal transmission of syphilis may take place, that is, that the organism occurs in the semen and either enters the conceptional spermatozoon or that both parasite and spermatozoon separately penetrate the ovum. Owing, however, to the large size of *Spirochæta pallida* many have held that for physical reasons it is impossible or at least improbable, that *Spirochæta pallida* infects a spermatozoon, although it may invade the ovum.

Balfour[4] states that *Spirochæta gallinarum* of Sudanese fowl spirochetosis has a granular as well as a spiral stage and Leishman,[5] Blanc,[6] Fantham,[7] Nuttall,[8] and Hindle[9] also entertain the belief that *Spirochæta gallinarum* and *Spirochæta duttoni* adopt a granular form under certain conditions, and that a spiral form can develop from these granules which have been variously called coccoid bodies, infective granules, or spores. Hindle observed in histological studies of ticks that they undergo segmentation, suggesting a process of sporulation. Todd and Wolbach[10] maintain that these granules are not specific and may be found in non infected ticks but Fantham points out that the granules of normal ticks are not identical with the coccoid bodies of infected ticks.

Of interest in this connection are likewise the investigations of Meirowsky,[11] who has described buds along *Spirochæta pallida* in cultures which he believes are concerned in the processes of division and multiplication. It is possible that these bodies are artefacts, but I have seen them very distinctly in cultures of *Sp. pallida* prepared in my laboratory by Miss Clara Kast and they are of much interest in relation to a possible resting stage of *Sp. pallida*. Noguchi[12] has also described peculiar, highly refractile, round bodies which is very often found attached somewhere along the side of the body of the organism.

Since 1915, McDonagh[13] has suggested that the spiral form was only the male phase of a protozoön and that the life cycle of *Spirochæta pallida* commences with a spore or sporozoite which enters a connective tissue or endothelial cell as its host followed by a process of budding giving rise to several bodies, which later become differentiated into male and female elements. McDonagh has accordingly designated the parasite of syphilis as *Leukocytozoön syphilidis* and while his work lacks general confirmation, yet when considered along with the investigations and observations briefly summarized above, is deserving of further study.

It is well known that the syphilitic testicle of a rabbit may show no spirochetes when the secretions secured by puncture are carefully and repeatedly examined with the dark field method during the resting stage of the cycle of orchitis in this animal; yet inoculation of an emulsion of this tissue into the testicles of fresh animals may result in infection although the percentage of "takes" is not as high as when inoculation is done with tissue containing numerous actively motile organisms. Of course, there is always the possibility in tests of this kind of overlooking the presence of a few spirochetes since it is obviously impossible to include every bit by dark field microscopic examination. Filtration of emulsions of such latent and of actively syphilitic tissue followed by injection of the filtrates into the testicles of rabbits have yielded negative results which speaks against a granular stage of *Spirochæta pallida* to the extent of a filter passing virus being produced; of interest in this connection, however, is the report of Artzt and Kerl[14] who found the secretions of erosive lesions of three patients free of spirochetes and yet infectious for rabbits, producing testicular lesions upon inoculation.

These observations show, therefore, that *Spirochæta pallida* may be but one phase in the cycle of development of the parasite of syphilis and that there may be a spore or granular stage which we have no means at present of recognizing. If such were proved to be the case, it is possible that the organism may be in the latent lesions which, when examined histologically, shows no spirochetes. Likewise a granular stage would afford a ready means for explaining the seminal transmission of syphilis as also maternal or placental transmission. The subject is not without interest likewise, in connection with chemotherapy and especially in relation to the treatment of the so-called "Wassermann-fast" cases of syphilis.

Mechanism of Primary Infection in Acquired Syphilis.—Syphilis is always acquired from human beings, either by direct or indirect contact, since there are no natural intermediate hosts or carriers of *Spirochæta pallida* among the lower animals. In the majority of instances infections occurs by direct contact with open lesions and their secretions containing *Sp. pallida.* These lesions are usually situated about the genital organs, the lips or in the mouth.

Infection may occur by intermediate contact, but in practice such instances are decidedly uncommon. Eating utensils and drinking cups used immediately after a syphilitic with open lesions in the mouth and contaminated with saliva are most dangerous. *Spirochæta pallida* dies quickly when the secretions become cold and dried and infections from toilet seats and towels are unlikely and rare in actual practice. An individual may accidentally and unknowingly become an intermediate carrier; for example, Schamberg has recorded an instance where a young man contracted syphilis of the lips by kissing a girl, who in turn had been kissed a short time previously by a syphilitic male. Practically any part of the skin or a mucous membrane is susceptible to infection with *Spirochæta pallida.* In over 90 per cent. of cases infection occurs about the genital organs. Extragenital infections most commonly occur about the lips, mouth and fingers, although infection may occur in the eye, nose and practically any part of the body. The scalp is probably less susceptible than non-hairy portions of the skin and the same is true of the rabbit, which is infected with difficulty except in the eye, scrotum and testicles. It is commonly stated that extragenital lesions are less common in the negro; for example, Hazen[15] reports that in over 3000 cases of syphilis seen by him in the colored race, only three presented extragenital lesions and it may be that in this race there are agencies in the skin affording some protection against *Sp. pallida,* although this is certainly not true of the mucous membranes of the genital organs of either sex. The negro in his sexual relations is less given to amatory practices and this may account for the lesser frequency of extragenital infections in this race. Reasoner,[16] however, suggests that the chancre is a tissue reaction of defense and that in the negro this reaction or defense to initial infection is but poorly developed outside of the genitalia and that extragenital infections may occur more frequently but are not discovered.

Infection in syphilis is ordinarily the result of contact with lesions and secretions containing *Spirochaeta pallida.* The lesion may be so small, however, as may easily escape detection and particularly when it occurs about the genital organs of women. Syphilitic men with no open lesions are still infectious by way of their semen and women are commonly infected in this way; in these cases *Sp. pallida* may be derived from the testicles which are so commonly infected in men and if such is the case, these testicular lesions are potentially open sources of infection.

May men be infected by sexual intercourse with women presenting no demonstrable open lesions about the genitalia? In other words, is the

woman presenting no demonstrable lesions or symptoms of syphilis other than a strongly positive Wassermann reaction infectious? Of course, it is well known that under these conditions she may transmit the disease to a fetus in the uterus, but is she infectious by ordinary sexual contact? In practice instances of such infections apparently occur, but it is almost impossible to be sure that a minute open lesion is not present about the cervix or in the folds of the vaginal mucosa. I do not know of any investigations of the vaginal and cervical secretions of such women for *Spirochaeta pallida* by rabbit inoculation tests, but such studies are advisable for shedding light upon this question. My belief is that *Sp. pallida* does not occur in the genital secretions of the woman unless an open lesion is present, although it is known that she may excrete *Sp. pallida* in the secretions of the mammary glands.

Experience teaches, therefore, that *Sp. pallida* is not ordinarily transmitted except by contact with open lesions or secretions of these. Such lesions are usually chancres and the cutaneous and mucous membrane lesions of the clinical secondary stage of syphilis. Tertiary lesions and their secretions are likewise infectious, but since they usually contain but few organisms, the infectiousness is only slight and may be altogether absent. The semen of syphilitic men may be infectious at any time after the primary stage, an instance of infection of a woman by the deposition of semen upon the labia being recently recorded by Moore and Keidel,[16a] but the ordinary body secretions as the saliva, perspiration and genital secretions of both sexes are probably not infectious in the absence of open lesions. Engman and Eberson[37] examined the nasal secretions of 24 syphilitics with negative results. *Spirochæta pallida* may be excreted in the urine, however, of either sex as indicated by the investigations of Vorpahl,[18] Hoffman,[19] Lévy and Guiél,[20] Fiessinger and Huber[21] and definitely proven by Warthin.[22] The latter found that this spirocheturia is most likely to occur during the spirochetemic stages of syphilis and is usually associated with degenerative lesions of the epithelium of the convoluted tubules rendering them more pervious to the passage of the organisms. It is possible that in women the urine may be a source of infection during sexual contact, but I do not know of any recorded instances of infection ascribed to this source. During the active stages of syphilis the mammary secretion of women may likewise contain *Sp. pallida*, indicating that when spirochetes are present in the blood they may find their way into the urine and to a lesser extent the milk, and possibly prove sources of infection in the absence of demonstrable open lesions.

It is commonly stated and quite generally accepted that *Spirochæta pallida* cannot produce infection of the skin or a mucous membrane unless the barrier of epithelium is first broken. Experiments with rabbits and monkeys and autoinoculation of human subjects consisting of rubbing *Sp. pallida* into the skin have commonly failed to produce infection. However, application of *Sp. pallida* to the vaginal mucosa of a rabbit presumably unbroken, yielded Reasoner[23] a positive result and Brown and Pearce[24] have succeeded in infecting the eyes of several rabbits by dropping *Sp. pallida* into presumably normal conjunctival sacs. Balzer and Barthelemy[25] have expressed the opinion that *Sp. pallida* deposited on normal integument, may under favorable conditions of warmth and moisture, proliferate, and penetrate the epidermis. Of course it is impossible to exclude the possibility and probability of minute abrasions of the skin and mucous membranes preceding infection with syphilis and for this reason it may never be possible to settle the question in a decisive manner whether or not pallida may gain access to the inter-epithelial lymph spaces through an absolutely intact layer of epithelial cells, but personally I believe this may occur on thin mucous membranes and especially if virulent *Sp. pallida* gain access to the glands.

From the standpoint of chemotherapy, this brief review of the mechanism of infection in acquired syphilis is of interest in relation to the prevention of

syphilis by the local destruction of *Sp. pallida*. This subject will be considered in more detail in Chapter LXX, but here it may be stated that the application of ointments of mercury or even thorough cleaning after exposure with soap and water may effectually kill *Sp. pallida* before deep invasion has occurred. This system of prophylaxis has been especially applied to men with a considerable degree of success providing the prophylactic measures are applied within an hour after exposure. Women are less frequently protected, because of the greater difficulty of applying the prophylactic procedures. The same measures may be applied when extragenital infection is feared. I have known two men, escaping a genital infection after contact with syphilitic women presumably due to the application of calomel ointment, to contract syphilis of the lips, and the application of prophylactic measure should not be neglected when extragenital infection may occur.

When more than three or four hours have elapsed after exposure reliance upon local prophylaxis in either sex cannot be placed upon local measures alone; under these circumstances arsphenamin or neoarsphenamin should be administered, as likewise to women who fear seminal infection after contact with Wassermann positive men.

Mechanism of Primary Infection in Maternal and Congenital Syphilis.—Syphilis of the woman presents certain peculiarities as yet little understood. In a broad and general manner the disease is not ordinarily as severe in her as in the male. The chancre may be and frequently is, so small and inconspicuous as to escape detection; the adenopathy and cutaneous lesions may be just as severe, but she is more likely to escape tertiary lesions of the nervous and cardiovascular systems. Probably this is due to the fact that heretofore she has not been subjected in the same degree as men to the wear and tear of these organs, which doubtless favors the localization and activities of *Sp. pallida* in these tissues. The latent periods in the tertiary stage are usually quite prolonged and in not a few instances the only symptoms for years and years are positive Wassermann reactions and the birth of frankly syphilitic children or children below par in general health. Even when there are reasons for strongly suspecting syphilis as a result of giving birth to syphilitic offspring, the Wassermann reaction is frequently negative with the total absence of lesions and symptoms indicating that some mechanism is operative in holding in check the activities and virulence of pallida in her tissues. Doubtless immunological processes are operative in women as a result of pregnancy which are not developed in men and childless women, but these will be discussed in more detail in Chapter XXXVII.

Undoubtedly women are infected with *Sp. pallida* in the semen of syphilitic men and especially during the first four years of the disease. It is well known that the testicles are commonly involved after the primary stage. In both man and the lower animals *Sp. pallida* frequently locate in these tissues although my colleague Dr. Saleeby, has found almost no evidence at all of syphilitic infection of the seminal vesicles of some twenty odd cases of tertiary syphilis, removed at necropsies and examined histologically. Neisser[26] states that in his experiments with apes "it appeared that the testicles acted particularly well and long as depots of the virus." Nichols[27] observed that after the intravenous injection of *Sp. pallida* in rabbits, the testicles were frequently the only organs to develop lesions. Symmers[28] observed chronic interstitial orchitis in 67 or 39 per cent. of a series of necropsies upon 171 male subjects with late acquired syphilis and Warthin[29] was frequently able to demonstrate *Sp. pallida* in testicles presenting no gross lesions. As stated by Herman and Klauder[30] clinical syphilis of the testicles is rare, that is, the presence of demonstrable lesion and particularly the typical "billiard

ball" lesion of chronic fibrosis is seldom encountered but nevertheless, histological examination of the testicles of syphilitic subjects shows that they are more frequently involved than indicated clinically. Syphilis of the prostate gland on the other hand, is quite rare as indicated by a recent analysis of the literature by Thompson,[31] and syphilis of the seminal vesicles has not yet been demonstrated.

Despite the frequency with which the testicles may be involved, the semen from syphilitic men frequently is not infectious for rabbits when injected into the testicles. Finger and Landsteiner[32] in a series of four men found *Sp. pallida* in the semen of two cases, one with orchitis and a second without demonstrable involvement of the testicles. Uhlenbuth and Mulzer[33] and Neisser and Hoffmann[34] have recorded additional positive findings in the semen during the active stages of syphilis and Engman and Eberson[35] found active, virulent *Sp. pallida* in the semen of two of a series of seventeen subjects with latent syphilis. Klauder[36] inoculated rabbits intratesticularly with 1 to 2 c.c. of semen from each of twenty-two subjects (one in primary stage, eight in secondary stage and thirteen in latent and tertiary stages) with negative results in all. Of course these examinations were usually made with one specimen from each subject, whereas it is easily possible and indeed probable, that the semen may be infectious at one time and not at another.

At any rate, it is well known that women may be infected with the semen of syphilitic men presenting no demonstrable lesions or symptoms of syphilis and even regarded as "cured." I do not know of a single instance, however, of a primary lesion being found in these cases. It is generally believed that the women is infected in a secondary manner; that is, *Sp. pallida* infects her ovum and that she in turn is gradually infected by the syphilized product of conception. I believe it is possible, however, for the spirochete to infect her directly without impregnation and without the production of a demonstrable primary lesion, the parasites gaining access to her lymphatic system by way of the endometrium. The resulting disease, however, is generally latent and may present nothing but a positive Wassermann reaction for many years. The causes and nature of this latency are, however, unknown. Possibly the parasites have been rendered comparatively non-virulent by residence in the tissues of the male or by reason of some profound alteration in their life cycle. Probably a syphilitic fetus aids in the development of immune principles in the woman counteracting the proliferative activities, virulence and dissemination of *Sp. pallida*, but there is no direct evidence of such. Possibly the secretions of the endocrine glands of the woman exert a restraining influence upon *Sp. pallida* as suggested by Montgomery,[37] who states that iodothyrin of the thyroid gland may be responsible since disturbances and activity of this gland is comparatively common among women.

The mechanism of prenatal or congenital syphilis is frequently a puzzling phenomenon. Of course a woman contracting syphilis after conception may transmit the spirochetes to the fetus any time up to the seventh or eighth months, the organisms passing from the maternal to the fetal blood. After the eighth month the child commonly escapes by being born before the spirochetemic stage of the disease has been well-developed in the mother. Likewise a syphilitic woman is always apt to transmit *Sp. pallida* to her child in the uterus for many years, the parasites being transmitted to the fetus by way of the blood in just the same manner as they may progressively invade any of her own tissues and organs. If the infection is latent in the mother, the child may escape infection but anything that stirs up the infection in the mother increasing the multiplication and virulence of the spirochetes

with invasion of the lymph and finally of the blood, increases the danger and likelihood of infection of the child. A child may likewise contract syphilis during birth if the mother happens to have an open lesion about the genital organs at this time.

But is there a strictly paternal form of transmission in prenatal syphilis? In other words, may the father directly infect the ovum at the time of its conception? Clinically this is believed by many to be possible and that the child may be infected and the mother escape. From the biological standpoint, however, paternal infection of the ovum is doubtful and at any event, infection of a child without subsequent infection of the mother is very improbable.

The head of a spermatozoön ordinarily measures 5 microns in length, 4 in breadth and 2 in thickness; *Spirochæta pallida* measures from 6 to 14 microns in length and from 0.2 to 0.5 in thickness. It is possible, therefore, that the head of a spermatozoön may mechanically carry a spirochete into an ovum which approximately measures 5 microns in size, but this does not seem to be probable. However, it is possible as previously discussed, that a granular stage of *Spirochæta pallida* may exist and if such is true, direct infection of the ovum may be readily understood.

It is my opinion that if an infectious granular or spore stage of *Sp. pallida* does not exist, that in paternal transmission of syphilis, *Spirochæta pallida* in the semen is taken directly into the uterine canal followed by infection of the pelvic lymphatics of the mother with secondary infection of the fetus. The end result is the same as if the spirochete invaded the ovum direct with a spermatozoön, only if this hypothesis is correct, the woman is always infected primarily and the fetus secondarily rather than the fetus primarily and the mother secondarily.

The subject of maternal and fetal syphilitic infection is of great interest and importance in relation to chemotherapy and will be discussed in more detail in Chapter LXXVII. Here it may be stated that a syphilitic father does not always transmit the disease. An abundance of clinical evidence shows that during the latent and tertiary stages he may beget apparently non-syphilitic children and we know that the semen may not contain *Sp. pallida* infections at least for the testicles of rabbits. But, however, it is also known that in some cases the testicles of the father may be invaded with *Sp. pallida* even though they appear clinically normal and from this standpoint the uncured male is potentially liable to transmit the disease in his semen and is usually a fit subject for treatment.

For the same reason, the mother of a child to a syphilitic man is apt to be infected even though she is apparently free of symptoms and lesions. As previously stated, the woman under these circumstances presents the most striking degrees of latency, the mechanism of which has not been satisfactorily explained. For this reason I believe that such women likewise demand treatment and especially if the child shows any signs or symptoms whatsoever suggestive of syphilis. However, a uniform rule to treat all women bearing children to syphilitic fathers would probably include some women who are not syphilitic; this is especially true if many years (more than five) have elapsed since the father's primary infection and if he has had some treatment and if the infection was clinically latent (although the Wassermann reaction may be positive) at the time of conception.

Theoretically every child of a syphilitic father or a syphilitic mother or both, should be treated for syphilis at least for a brief time, even though apparently free of lesions and symptoms. Children born without manifest lesions may still be infected and in such cases the latency is analogous to

latency in the mother. Our knowledge of the clinical symptoms and lesions of latent congenital syphilis is being constantly increased and we now know that in children certain lesions and symptoms are syphilitic which a few years ago were not regarded as such. However, a uniform rule to treat all children for syphilis born of a father who may show nothing more than a positive Wassermann reaction would be practically sure to include some who were not actually infected. The same is true but to a much lesser extent, of children born of a woman who presented nothing but a positive Wassermann reaction, but the chances of a child escaping under these conditions is so slight that it should be the rule to treat every such child regardless of the fact that clinically there are apparently no signs of infection.

Mechanism of Systemic Infection in Syphilis.—Within forty-eight hours after exposure and inoculation the spirochetes of syphilis have probably gained access to the lymph spaces in the deeper layers of the skin or mucous membrane and it is likely that a few parasites have already invaded the nearest lymph glands; invasion of the glands is surely the case in the majority of infections after the primary lesion has developed.

The spirochetes apparently proliferate rapidly in the lymph and lymphatic glands and being swept into the venous blood are carried to the heart, the lungs and arterial blood followed by distribution through the coronaries and other arteries. Subsequently they are lodged in the arterioles and invade the perivascular spaces, setting up there a train of pathological changes consisting mainly of chronic hyperemia, lymphocytic, plasma cell and serous infiltration accompanied by necrosis of the cells of the tissue invaded and usually ending in fibrosis of the lesions of long duration.

From these depots of infection the spirochetes may progressively involve an organ by direct extension along interstitial and especially lymphatic spaces, yielding uniformly distributed and fibrotic lesions. From these localized or general lesions, organisms are likely at any time to be swept along with the lymph into the venous blood followed by arterial distribution to parts of the same or distant organs with localization by preference in tissues or organs the seat of previous injury or active hyperemia, including the placenta and fetus in the case of pregnancy. From the standpoint of this localization of spirochetes from the primary lesion or from these secondary depots, the subjects of special strains and selective localization are of much interest and importance, which I shall discuss in the succeeding chapter.

Spirochetemia or the presence of spirochetes in the blood, is, of course, most marked during the few weeks following the development of the primary lesion and before the development of the cutaneous and mucous membrane lesions of the clinical so-called secondary stage of the disease, but subsequent to this and at any time thereafter, temporary blood infections may occur and especially if active lesions are present anywhere in the body. Since clinically latent lesions may be, therefore, foci from which spirochetes are distributed to other organs and tissues, it would appear that the syphilitic is always a fit subject for treatment unless this is contraindicated by senility, by pathological changes in vital organs reducing tolerance for spirocheticidal compounds or by syphilitic lesions so situated or developed and especially in the central nervous system, that therapeutic success cannot be expected and it is decided to leave well enough alone. From the standpoint of chemotherapy best results are secured of course, before lesions become fibrotic, this subject being discussed in more detail in Chapter XXXVII dealing with the pathology of syphilis in relation to chemotherapy.

Relation of Trauma and Tissue Injury to Syphilitic Infection.—Trauma in a broad sense probably bears an important relation to the dissemination and localization of *Spirochæta pallida*. I have already mentioned that trauma greatly predisposes to initial infection and subsequent to this time, trauma or tissue injury in a broad sense and caused by many different agents in an important factor in the future welfare of the infected individual.

Physical trauma as long continued irritation at one point, fractures, surgical operations, etc., may apparently favor the development of *Spirochæta pallida* in these areas or if the tissue injury involves a focus of syphilitic infection, the spirochetes may be stimulated into reproductive activity and virulence. Klauder[38] has recorded cases of gummatous ulceration developing at the site of lacerations, after repeated and long continued trauma and after injury to the testicles; also of provocative Wassermann reactions following a surgical operation and the injection of antitoxin, both procedures apparently stimulating latent foci of spirochetes into activity. Gougerot and Clara,[39] Ramond and Postina[40] and Coues[41] have recorded instances of lesions developing in the skin, muscles and bones at the site of wounds and contusions inflicted during warfare. Estes,[42] Gelle',[43], Charpy[44] and others have reported instances of non union of fractures due to syphilis and presumably the presence or localization of *Sp. pallida* in the periosteum and marrow. Klauder states that there is no doubt that trauma can be ascribed as a precipitating cause of paresis and in an analysis of sixty one cases among admissions to the Boston Psychopathic Hospital, symptoms of paresis followed recent trauma in three cases. In other cases physical exhaustion, sunstroke and lead poisoning appeared to initiate the symptoms of paresis. Osnato[45] has also reported cases of post-traumatic paresis developing within a few days to a few weeks after injury and Pighini[46] states that during the late war violet emotions and injuries of the skull and the dorsal column may have been the indirect cause of the appearance of some of the serious disorders among Italian soldiers, primarily due to syphilis. Southard and Solomon[47] state that on general grounds post-traumatic effects are not likely to be delayed more than three months after injury.

It is not difficult to understand that if an injury involves syphilitic tissue, the spirochetes may spring into renewed activity since the conditions for multiplication would be favored in the devitalized tissue and inflammatory exudates. Likewise, if injury should occur during or before spirochetemia, it is highly probable that localization in such areas would be favored by reason of hyperemia and cultural conditions. In a general way, any profound local or systemic injury would exert effects of this kind favorable to syphilitic infection and among general or systemic injuries I would include the effects of pregnancy, chronic alcoholism and other intoxications, excessive mental work, worry and exhaustion, etc., as factors reducing local or general resistance of an isolated organ or the body as a whole to the dissemination of *Sp. pallida*, the arousing of latent foci and the progression of syphilis.

In view of the widespread prevalence of syphilis it cannot be said that the development of syphilitic lesions at the sites of injuries is a frequent occurrence; this is readily understood when we keep in mind the intermittent character of the spirochetemia in syphilis and that traumatic injuries may only occasionally actually involve nests of *Sp. pallida*. Klauder, however, has thoroughly discussed trauma in relation to syphilis from the medico-legal standpoint, in which relation the subject is of considerable importance.

From the standpoint of the treatment of syphilis, the subject is likewise of considerable importance and especially in relation to tardiness in the healing of wounds and the non-union of fractures as well as again emphasizing the advisabiiity of treating latent cases of syphilis unless distinctly contra-indicated, if for no other reason than the danger that constantly exists of local or general tissue injury stimulating latent foci into renewed activity.

Pathogenesis or Mechanism of Production of Disease by Spirochæta Pallida.—By the pathogenesis of *Spirochæta pallida* I refer to the agencies by which these spirochetes actually produce the lesions of syphilis—that is, the mechanism of the production of the disease syphilis. We know that bac-

teria may produce disease by a wide variety of agencies as true exogenous toxins, endotoxins and aggressins, ferments, bacterial proteins, the products of necrosis of inflammatory exudates, etc. By what agencies are syphilitic lesions produced?

There is surprisingly little data on this subject. Clinically it is supposed that *Sp. pallida* produces a toxin or toxins to explain the anemia, loss of weight, general body pains and such general symptoms of infection in syphilis but no one has yet clearly demonstrated the existence and nature of these substances. From the pathological standpoint it appears almost certain that virulent *Sp. pallida* produce toxic substances in the tissues responsible for the necrosis of the cells of the tissue infected and for exerting a positive chemotaxis on small lymphocytes.

It is also possible that endotoxins in the nature of aggressins are produced, since phagocytosis of *Sp. pallida* is so rarely seen in sections of syphilitic tissue or smears of inflammatory exudates. Proteolytic ferments, however, apparently are not produced since caseation and liquefaction necrosis do not occur except in large and old lesions in which case vascular occlusion and loss of nutrition are primarily responsible. Syphilitic lesions in the skin and mucous membranes open to secondary bacterial infection frequently suppurate, but these effects are ascribed to the toxins and ferments of the bacteria rather than to spirochetic agents. In malignant syphilis, however, the large size and necrotic character of the lesions with profound symptoms of toxinemia, may be ascribed primarily to toxic substances elaborated by unusually virulent pallida.

From the standpoint of treatment it may be stated that all attempts have failed toward developing a successful method of serum therapy for the destruction of the spirochetes and the neutralization of their toxins. Some investigators claim that upon the rapid destruction of large numbers of *Sp. pallida* by such spirocheticidal agents as arsphenamin and neoarsphenamin, that poisonous products are released which may be responsible in part for the symptoms and lesions constituting the reaction sometimes following the administration of these compounds. Indeed, this is one of the oldest explanations of the mechanism of the arsphenamin reaction and in part it may be true in some cases at least, but I shall discuss this subject more fully in Chapter XLVII.

CHAPTER XXXVI

STRAINS OF SPIROCHÆTA PALLIDA IN RELATION TO THE TREATMENT OF SYPHILIS

It is of course well known that the clinical manifestations of syphilis are subject to wide variations in all stages of the disease. Even the primary lesion may vary from a slight superficial erosion which may escape detection, to a large phagedemic ulcer and the cutaneous and mucous membrane lesions may vary from so few in size and number as to almost escape detection to those that are large, numerous and even pustular. The late lesions, however, are the most variable in number and location. In some cases they are principally located in the tissues of the central nervous system producing paresis or tabes dorsalis as the predominating and principal lesions; in other cases these tissues seemingly escape while the myocardium, aorta, the skeletal system or other organs are heavily infected.

What are the determining factors? Do special strains of *Spirochæta pallida* exist with inherent transmissible selective affinities for the brain and nerve tissue in one case and for the cardiovascular or cutaneous organs in another? The subject is one of importance and especially so in relation to treatment and prognosis since there is considerable variation in the curability of these lesions, those of the brain and spinal cord being much more dangerous

and less amenable to treatment than those of the cutaneous and skeletal tissues.

Variations in the Virulence of Spirochæta Pallida.—In the first place, I believe it is to be granted that *Spirochæta pallida* varies considerably in virulence, by which is meant variations in the degree of invasiveness of the tissues, rate of multiplication and the production of those offensive agencies designated as toxins. It is known that this occurs in experimental infections of rabbits and that inoculation with spirochetes from active syphilitic lesions are followed by more rapid development of scrotal and testicular lesions than follows inoculation with spirochetes from old and relatively inactive lesions. Among the bacteria it is well known that variations in virulence occur and that the resulting diseases vary in clinical severity and duration accordingly without involving the question of specific strains; I can see no reason why the same may not be true of the pathogenic spirochetes including *Spirochæta pallida*. From the clinical standpoint it is commonly observed that inoculations with spirochetes from acute chancres and mucous patches results in the production of severer primary lesions than inoculation with organisms from older and latent lesions; in this connection it has been suggested that the virulence of *Spirochæta pallida* in the skin and bones may be reduced by the action of ferments and consequently rendered less invasive for the central nervous system. Malignant syphilis may not be necessarily due to infection with a particularly virulent strain of *Spirochæta pallida*, but rather a greatly reduced resistance of the victim to infection. The severity of all cases of syphilis among human beings and those produced experimentally in the lower animals, are doubtless influenced by the state of natural resistance of the host and the degree of defensive activity, but in addition we doubtless have variations in the virulence of the parasites themselves to account for the varying degrees of severity of the resulting lesions.

I believe, therefore, that inherent virulence of the strain of *Spirochæta pallida* producing the infection, together with the degree of local and general resistance offered by the host and more especially, the location of areas of reduced resistance in the host the result of trauma, previous disease or even of inheritance, largely determines the distribution and localization of spirochetes and consequently the clinical course of syphilis in any given case without involving the question of specific organotropic strains. However, a large amount of experimental work has been published lending support to the theory that specific strains of *Spirochæta pallida* exist and while these are not conclusive, they are worthy of the closest attention in view of the great importance of the subject.

Influence of Local Reactions upon the Distribution of Spirochæta Pallida. When *Spirochæta pallida* are deposited in the tissues either at the time of primary infection by direct inoculation through abrasions of the epithelial barriers or subsequently by the lymph and blood, the tissues of the host react to the invasions with the production of local reactions consisting of the usual cycle of inflammatory phenomena embracing hyperemia with serous and cellular exudation. This occurs with primary inoculation and the reactionary lesion is called a chancre; it occurs in the spirochetemic secondary stage and the lesions are called papular syphilids, mucous patches, etc. Exactly the same kinds of lesions occur in the internal organs hidden from view.

Each and every local reaction expresses the defense of the host to this parasitic invasion; it is Nature's means for resisting the infection. We know little or nothing of the exact nature and mechanism of the defensive forces at work in each of these foci, but investigations have shown that they apparently influence the multiplication, subsequent distribution and possibly the

pathogenic properties of the spirochetes. Evidently the power of tissue reaction varies in different organs during the early stages of the disease; in other words, during the spirochetemic stage of syphilis prior to the development of the secondary lesions, the parasites are doubtless distributed broadcast throughout the body, but in some tissues they apparently either do not find conditions favorable for survival or they are immediately destroyed by defensive agencies. Later in the disease these tissues may be invaded again and again with finally the successful establishment of foci of infection, particularly in areas of reduced resistance; but in this case, invasion is by spirochetes with acquired resistance to these defensive agencies and thereby capable of surviving and establishing infection. At any rate, even in paresis the other internal organs do not escape; syphilitic aortitis and myocarditis especially may be present as well as cutaneous and osseous lesions showing that the spirochetes are not specific for the nervous tissue alone, granting that specific tissue strains actually exist.

Nichols[1] has shown that removal of the local focus in one testicle of a rabbit favors development of syphilis in other and since then Brown and Pearce[2] have shown in a clear and decisive manner, that suppression or removal of a local testicular lesion in a rabbit favors the widespread distribution of the spirochetes in this animal. In other words, it would appear that in the local reaction to *Spirochæta pallida* in the initial chancre, the body cells of the host produce something which is not only inimical to the spirochetes in the lesion but which apparently holds in check the multiplication, distribution and pathogenic properties of those spirochetes already located in the neighboring lymphatic glands and other tissues.

Now clinical experience confirms the teaching of Fournier that human subjects developing large chancres followed by florid secondary lesions are less likely to develop infection of the nervous system and other internal organs and are more readily cured than subjects developing small chancres and poorly developed secondaries. In other words, clinical experience is in conformity with experimental work, showing that when the host is able to produce a large local reaction about invading spirochetes something is produced that tends to destroy or at least to hold in check the multiplication, virulence and distribution of the parasites.

Just what determines the degree of this local reaction is unknown. Neither do we know of any measures by which it may be increased for therapeutic purposes. It is apparently controlled by inherent forces of natural immunity and resistance, concerning which we know practically nothing at all insofar as syphilis is concerned. Apparently it bears no relation to general health; the strong and robust may have the small chancre and early neural infection while the frail and sickly may have the large chancre and delayed tertiary lesions with clinical escape of brain infection.

According to Marie and Levaditi the so-called neurotropic strains of *Spirochæta pallida* produce the small chancres in human beings and rabbits; it may be that the degree of local reaction is dependent upon the properties of the spirochetes and not upon the defensive agencies of the host. If such were true the degree and kind of local reaction would be evidence in favor of the existence of specific strains of *Spirochæta pallida;* but be this as it may, it would appear that the character of the primary local reaction (chancre) and the subsequent cutaneous and mucous membrane reactions (the secondaries) appear to influence the internal distribution and virulence of *Spirochæta pallida*, even though the character of these lesions may in itself be evidence of inherent tissue specificity on the part of different strains of pallida.

Trauma and Tissue Injury in Relation to the Distribution and Specific Strains of Spirochæta Pallida.—As discussed in the preceding chapter, trauma and tissue injury in a broad and general manner exerts an important influence upon the development of the late lesions of syphilis. It is readily understood how and why this is the case when the tissue injury involves a latent focus of *Spirochæta pallida* infection, the multiplication and even the virulence of the spirochetes being enhanced by a lowering of local resistance. But does tissue injury influence the localization of the parasites during the spirochetemic stages of syphilis?

In this sense I believe that the subject of tissue injury must be broadly interpreted. For example, the laborer engaged in heavy work with temporary, but frequently repeated, high blood pressures may injure his aorta or myocardium and favor localization of spirochetes in these organs. The individual engaged in severe and prolonged mental work, strain or worry may injure the tissues of the brain and favor localization of the parasites in this organ with the eventual production of paresis or some other syphilitic disease of these tissues, even though it may not be possible to evaluate the degree of predisposing tissue injury by morphological changes. Possibly even long continued eye strain due to errors of refraction may so influence vascular changes in the choroid and retina as to favor the localization of spirochetes in these tissues.

I believe that tissue injuries of this sort producing local areas of lowered resistance or long continued congestion influence the localization of the spirochetes not only during the primary period of spirchetemia following the chancre and preceding the cutaneous eruption, but also throughout the existence of uncured syphilis. As previously stated it is highly probable that temporary spirochetemias are of frequent occurrence even in the late stages of syphilis and trauma or tissue injury may continue to exert an influence upon localization of spirochetes throughout the course of the disease. In this manner we may explain the frequency of syphilitic mucous patches and glossitis in smokers; the squamous syphilids of the palms among those engaged in manual labor and the lesions developing after tatooing etc.; Chesney and Kemp[3] have recently shown in experimental syphilis of rabbits that *Spirochæta pallida* can be inoculated into granulating ulcers of the skin and that active proliferation of connective and epithelial cells greatly favors the multiplication of *Spirochæta pallida.*

Hereditary Influences in Relation to the Specific Strains of Spirochæta Pallida.—An additional factor of importance in relation to this question of specific strains of *Spirochæta pallida* is that of familial predisposition to parenchymatous neurosyphilis with special reference to paresis and tabes dorsalis. Older syphilologists frequently mentioned the tendency for these forms of syphilis to develop in members of the same family.

Recently Moore and Keidel[4] reported three families embracing eight members, all of whom acquired syphilis at different times and from different sources, yet all developed neurosyphilis. Moore and Kemp[5] subsequently studied two additional families. In the first, two brothers, acquiring syphilis from different women, at widely separated dates, developed general paresis. In the second family, the father acquired syphilis in 1900 and died in 1918 of paresis; his son contracted the disease in 1919, and in 1923 developed typical taboparesis. As stated by Moore and Kemp, the fact that in five families such an occurrence has been observed is too striking for mere coincidence; it would appear that in certain families, the nervous system is a joint of local reduction in resistance to *Spirochæta pallida.* Granting that such predisposition of the brain and cord to infection were transmissible, mere invasion of these tissues with *Spirochæta pallida* during the early or initial spirochetemic stage of syphilis would be sufficient to bring about localization without involving the question of specific neurotopism. Kemp and Poole[6] have recently stated however, that on the basis of studies on the incidence of neurospyhilis among the parents of congenitally

neurosyphilitic children in twenty familes, it was found that neurosyphilis was eight times as frequent among the mothers and over three times as frequent among the fathers of congenitally neurosyphilitic children as among the parents of children with congenital syphilis without demonstrable neurosyphilis. In their opinion this difference is sufficiently striking to suggest the existence of a neurotropic strain of *Spirochæta pallida* responsible for the production of neurosyphilis although familial predisposition to neurosyphilis may be a factor of equal importance in determining this type of the disease. Indeed as stated by Cooke and Jeans[6a] recorded instances of twins born to syphilitics, one of whom developed neurosyphilis and the other not, apparently constitutes evidence against the existence of a neurotropic strain of *Spirochæta pallida*.

Clinical Evidence Concerning Strains of Spirochæta Pallida.—Probably the strongest evidence in favor of specific tissue strains of *Spirochæta pallida* is derived from clinical studies of these kinds. Unfortunately, however, clinical studies and deductions are subject to much error and require great caution before adoption. Mention has already been made of the clinical relation between the small chancre, and the poorly developed or absent cutaneous lesions with the early development of visceral syphilis, including paresis and tabes. But these events may be explained just as well on the basis of the virulence (invasiveness) of *Spirochæta pallida*, the character of the local defensive reactions and the predisposing tissue injuries as upon the supposition that such infections are due to specific strains of *Spirochæta pallida*.

The strongest clinical evidence of neurotropic strains of *Spirochæta pallida* is based upon the few historical instances of doubtful authenticity, purporting to show the infection of different men with paretic strains of *Spirochæta pallida* from the same women; also the incidence of conjugal neurosyphilis which is the development of neurosyphilis among the wives of neurosyphilitic males or of the husbands of neurosyphilitic females.

Fischer[7] found only ten cases of conjugal neurosyphilis among the partners of 395 paretics but Meyer[8] and Hauptman[9] observed that about 30 per cent. of partners developed neurosyphilis. More complete studies by Plaut and Goring[10] have shown that 60 per cent. of the partners of neurosyphilitics are syphilitic; that 18 per cent. of the total number of partners are neurosyphilitic and that about 30 per cent. of the syphilitic partners are neurosyphilitic. These results, however, were based almost solely upon symptomatic evidences alone; studies including the routine examination of the spinal fluid for evidences of asymptomatic neurosyphilis have shown a higher percentage of neural involvements as indicated by the reports of Wile and Marshall,[11] Moore and Keidel[12] and Moore and Kemp.[13] The data offered by these investigators suggest the existence of a neurotropic strain of *Spirochæta pallida* as an etiologic factor in paresis and tabes, but not in diffuse cerebrospinal syphilis, in which cases evidence supporting the theory of special strain is lacking. While about 75 per cent. of the partners of neurosyphilitics develop syphilis, although in the majority of these the disease is latent and detected only by serological and other examinations of the blood and spinal fluid, in only a small number does the conjugal infection run true to the type of the partner; furthermore, it is entirely likely that if it were possible to examine more closely the other internal organs and especially the heart, aorta, kidneys, adrenals and testicles it would be found that the spirochetes were more generally distributed than alone to the brain, cord and meninges.

Sicard[13] has refused to accept the evidence indicating the existence of specific tissue strains of *Spirochæta pallida* and states that neurotropic strain is not likely to be transmitted from one person to another except during the chancre stage, inasmuch as the cutaneous and mucous membrane lesions are regarded as of uncommon occurrence. If this is true Sicard claims that neurotropic strains are destined to disappear, because the opportunities for

contagion are rare; but as a matter of fact syphilis of the nervous system is apparently increasing instead of decreasing. However, Sicard overlooks the fact that a syphilitic man may possibly transmit a neurotropic strain in his semen since temporary spirochetemias occur in neurosyphilis just as in other clinical types with involvement of the testicles. It is likewise true that a neurosyphilitic woman may develop open lesions with the infection of her sexual partner, or of her children by direct placental transmission of the strain during temporary periods of spirochetemia. While the danger of infection for the spouse increases as the date of infection in the one acquiring syphilis approaches the time of marriage, yet it is well known that neurosyphilitic patients may be infectious for many years, in spite of the absence of demonstrable open lesions. From the clinical standpoint, therefore, the theory of the existence of neurotropic strains of *Spirochæta pallida* has some support but the evidence is not conclusive.

Experimental Syphilis of the Rabbit in Relation to Specific Strains of Spirochæta Pallida.—The experimental work upon which the theory of specific tissue strains of *Spirochæta pallida* is based, was first conducted in this country. From the standpoint of morphological differences in strains Noguchi[14] first described thin, thick and average types and what is more important in relation to the possibility of specific strains, that the thin type usually produces rapidly growing and diffuse lesions. Since then it has been shown, however, that these morphological types do not bear any constant relation to the generalized lesions of syphilis in the rabbit or human being, Reasoner,[15] for example, reports that no morphological differences were discernible among those strains producing choroiditis and chorioretinitis of rabbits and those that did not. Pfeiffer[16] has reported that both thick and thin forms have been observed among spirochetes recovered by him from four cases of human paresis and Levaditi and Marie have not noted any constant morphological characteristics of their so-called dermotropic and neurotropic strains.

In 1913 Nichols and Hough[17] secured a strain of *Spirochæta pallida* from the spinal fluid of a case of nervous relapse following the administration of salvarsan in the secondary stage of the disease. The parasite was of the thick variety, produced hard, nodular lesions in the testicles of rabbits and was characterized by high invasive power with a tendency to produce generalized lesions, and especially of the skin and eye. Subsequently Nichols[18] expressed his belief that while all strains probably localize indifferently in certain organs during the early septicemic stage, in addition, certain strains probably have an especial localizing power.

Reasoner subsequently reviewed this work, reporting upon the characteristics of this and additional strains, two of which likewise produced choroiditis and chorioretinitis. Fourteen other strains from chancres and mucous patches did not produce these lesions. From a large number of experiments on rabbits he concluded that it is possible to demonstrate satisfactorily fixed differences in various strains of *Spirochæta pallida* as found in the lesions produced in rabbits and that it is possible to produce involvement of nervous tissue without actual intracranial inoculation. He was careful enough to add, however, that in evaluating these results in relation to human syphilis, individual resistance of the infected person must still be considered as a factor in the localization and development of the disease.

Since then the strain of *Spirochæta pallida* isolated by Nichols and Hough has been widely employed in this country for experimental work with rabbits. It still maintains a high degree of invasiveness and as stated in Chapter XXI, Brown and Pearce have employed it in much of their work with the production of widespread generalized lesions, especially after suppression of the primary lesion. I have likewise employed it in my work for the past eight years with essentially similar results. It cannot be said, however, to possess any type specificity other than a high degree of invasiveness. Zinsser and his colleagues have compared its pathogenicity along with five other strains isolated from mucous patches and chancres and found the lesions essentially similar for all.

In Europe the investigation of Levaditi and Marie[19] upon specific types of *Spirochæta pallida* have attracted a great deal of attention. Both are strongly of the opinion that

there are two independent strains, one of which they term the *dermotropic* and the other the *neurotropic*, in accordance with their selective localization. They have suggested that the neurotropic strain may be derived by evolution from a common parent by propagation in the nervous tissue giving rise to a really new strain that may persist like a mendelian variant, thereafter functioning as such instead of reverting to its former characteristics.

They claim that the dermotropic and neurotropic strains may be differentiated according to the lesions produced in rabbits, the neurotropic strains having a longer period of incubation and producing superficial and erosive papulosquamous lesions in contrast to the deep, ulcering lesions with hard bases produced by the dermotropic strains. The neurotropic strains according to these investigations attack epithelium with a special affinity for the prickle cells while the dermotropic strains produce vascular and sclerotic changes. The latter have been found pathogenic for the lower monkeys, anthropoid apes and human beings, while the neurotropic strains were found non-pathogenic for these when inoculated cutaneously.

What has been most striking to me has been their reports indicating that rabbits infected with the dermotropic strains are not immune to superinfection with neurotropic strains and the reverse. Among human beings there is almost an absolute immunity to re-inoculation with *Spirochæta pallida* after the lesions of syphilis are well developed, but according to Levaditi and Marie, a human being infected with a neurotropic strain would not be immune to a dermotropic strain and the reverse. Among those who regard *Spirochæta pertenuis* of yaws a distinct and different organism from *Spirochæta pallida*, great emphasis is placed upon the fact that a monkey or rabbit infected with yaws is susceptible to syphilis and the reverse, that human cases of yaws may contract syphilis and that syphilitics may contract yaws. If Levaditi and Marie are correct, however, the significance of these immunological differentiation is greatly reduced and weight is added to the view that *Spirochæta pertenuis* is really a dermotropic strain of *Spirochæta pallida.* Levaditi and Marie have mentioned in this connection that immunity to any one of the three different spirochetes of European, African and American relapsing fevers, does not protect from infection with the others, in spite of morphological resemblances and the similarity of the disease which they produce.

Fournier and Schwartz[20] have described two kinds of scrotal lesions in rabbits which appear to be constant. One type produces a herpetiform, erosive lesion after an incubation period of fourteen to twenty-one days, and lasting about three weeks, while the other produces a deep, indurated ulcer after an incubation of one to one and one-half months which persists for one to three months.

Pagniez[21] and numerous others have also expressed their belief in the existence of a neurotropic strain but since the discovery of *Spirochæta cuniculi*, which produces a spontaneous venereal disease of rabbits with superficial papulosquamous lesions strikingly similar to those produced by the neurotropic strains, one cannot escape the suspicion that these spirochetes may have been confused with *Spirochæta pallida;* however, in a recent paper by Levaditi and Marie[22] this possibility was considered and apparently excluded to their satisfaction. Laumonier,[23] Sicard,[24] Sezary,[25] Marchand,[26] Plaut and Mulzer[27] have refused to accept the evidence and theory of the plurality of strains of *Spirochæta pallida*, believing that a difference in the host rather than in the organism itself accounts for the variance in results.

More recently Wilkes-Weiss, Richter and myself[27a] have studied this problem in a different way, namely, by immunizing rabbits with six different cultures of *Spirochæta pallida* including the Nichols-Hough strain, and then studying the question of immunological specificity by means of cross agglutination and complement-fixation tests after the manner by which pneumococci and other organisms have been classified into groups. Our results however, have been of a negative character, that is to say, we were unable to demonstrate any evidences of immunological specificity on the part of the different strains employed by us.

But I believe that more work is required to settle this question and especially cross immunization tests as conducted by us to determine more accurately the relation or lack of relation between strains. It is especially necessary to be absolutely sure that *Spirochæta cuniculi* is not included.

Concerning agglutinin production, it appeared in my experiments that cultures of many different strains showed practically no variations in antigenic activity for rabbits. I believe that the experimental evidence in favor of accepting a specific neurotropic strain of *Spirochæta pallida* is as yet inconclusive. Strains of higher invasive power than the average may be isolated, as originally accomplished by Nichols and Hough, and for which they claimed this attribute only insofar as strain specificity was concerned. Further than this, however, I do not believe conclusions are warranted, since the distribution and localization of *Spirochæta pallida* are so greatly influenced in the experimental animal by the inherent invasive qualities of the spirochetes together with the nature and degree of the local primary reaction and the occurrence of trauma and tissue injury.

Immunological Phenomena in Syphilis in Relation to Localization of Spirochæta Pallida.—After infection with *Spirochæta pallida* has occurred do immunological processes determine or influence the subsequent localization of the parasites? We have already discussed the importance of tissue injury as a predisposing factor in localization but may tissues and organs escape infection by possessing a higher degree of resistance than the average? Or may the reverse occur with the production of allergic sensitization of some organs and notably the nervous tissues, as the result of long continued infection, with predisposition to the localization of *Spirochæta pallida* as suggested by Noguchi?[28]

Clinical experience shows that practically every organ of the human being is subject to infection with *Spirochæta pallida*, but some organs undoubtedly escape infection in a very much higher percentage of cases of syphilis than other organs. The prostate gland for example, is rarely involved insofar at least as clinical and pathological changes are concerned whereas the testicles are frequently infected; syphilis of the seminal vesicles has not so far been described. The skeletal muscles, likewise, usually escape infection unless areas of local resistance due to tissue injury predispose to localization of *Sp. pallida*.

It is possible, therefore, that during the spirochetemic stage of syphilis spirochetes are unable to localize in some tissues because these possess a sufficient degree of resistance to prevent invasion or, are lacking in suitable pabulum. The nature of this resistance, however, is unknown but one thinks of factors unfavorable to the nutrition of spirochetes or of spirocheticidal metabolites in this connection rather than destruction by phagocytosis or spirocheticidal antibodies.

It is possible but scarcely probable that allergic sensitization of the tissues of the central nervous system or of other organs may favor the final localization of spirochetes in such tissues during chronic infections. Under these circumstances foci of *Spirochæta pallida* in the lymph-glands, myocardium, etc., may elaborate protein products capable of sensitizing other tissues. If such occurred it is readily understood how spirochetes brought to these tissues by the blood would find a favorable reception and soil for localization owing to the well-known affinity of sensitized tissues for the antigen. In this connection it may be mentioned that one type of reaction sometimes following the administration of arsphenamin has been ascribed to the effects of *Spirochæta pallida* products suddenly released through the disintegration of the parasites by the medicament upon sensitized tissues. Likewise the occurrence of the *luetin* skin reaction lends weight to the supposition of sensitization in syphilis; but recent investigation by Stokes,[29] Greenbaum and myself[30] have shown that the skin reaction to luetin in syphilis may not be allergic at all, but an expression of heightened reactivity

of the skin in this disease to the injection of most any substance including the culture medium employed for the preparation of *luetin*.

Relation of the Question of the Plurality of Strains of Spirochæta Pallida to the Treatment of Syphilis.—I have briefly reviewed the evidence for and against the theory of plurality of specific tissue strains of *Spirochæta pallida* because the question is not without much interest and importance in relation to the treatment of syphilis. This relation refers not only to the admitted difficulties attending the amelioration if not the cure of neurosyphilis but more importantly to the influence of inadequate treatment of syphilis in its early stages upon the development of visceral syphilis with special reference to neurosyphilis.

It is still too early to express any opinion concerning the influence of the treatment of syphilis with arsphenamin and allied products upon the development of paresis, tabes and other forms of neurosyphilis. An interval of many years must elapse before material sufficiently large to be of value can accumulate. As shown by Mattanschek and Pilcz,[31] about 4.67 per cent. of syphilitics treated with varying degrees of thoroughness with mercury and iodids develop paresis, while 2.73 per cent. develop tabes. In their experience the majority of paretics were individuals in whom the course of syphilis appeared to be mild, regardless of the kind and amount of treatment given; no relation could be shown between thoroughness of treatment and the time of onset of paresis, but the percentage of syphilitics developing paresis and tabes was much less among those receiving thorough and intermittent treatment than among those receiving little or no treatment. Moore and Kemp also found that with regard to the syphilitic spouses of neurosyphilitics studied by them, none had received any previous treatment. It would appear, therefore, that early and adequate treatment of syphilis safeguards some against neural infections; this subject is discussed, however, with more detail in Chapter LXIX.

Thorough treatment of syphilis in its early stages is required for the prevention of neural infection; inadequate treatment may actually increase the chances of this dreaded accident. As previously stated the experimental work of Brown and Pearce has shown that treatment of the rabbit with testicular lesions of syphilis, insufficient to effect complete cure but with suppression of the local lesion, results in favoring the dissemmation of the spirochetes. Apparently the local lesions produce immunity principles or in some manner influence the spirochetes, tending to delay or prevent the progressive involvement of other organs and tissues and anything which diminishes this local reaction short of complete destruction of all parasites may actually favor the general distribution of the organisms. Keidel[32] has recently stated that in human syphilitics a similar phenomenon may be operative and that the occurrence of neurosyphilis or syphilis of other internal organs bears a relation to the occurrence and degree of the local reaction (chancre and secondary lesions) as well as to insufficient and inadequate treatment, the latter serving only to suppress these local lesions, without complete destruction of all spirochetes, and thereby doing more eventual harm than temporary good.

Some have claimed that the difficulties attending the treatment of neurosyphilis and especially paresis and tabes, may be further evidence of the plurality of strains. It is difficult, however, to understand how and why this should be the case; the acceptance of such a theory presupposes that the neurotropic strain or strains had acquired a fastness or resistance to the usual antisyphilitic remedies in common use. It is possible and indeed probable, that the spirochetes acquire some degree of fastness during treat-

ment owing to the fact that many cases of neurosyphilis are under treatment for long periods of time, but this possibility has no bearing at all upon those cases of neurosyphilis infected at a time antedating the introduction of arsphenamin and allied products in the treatment of syphilis, which includes a large percentage of the cases of paresis and tabes encountered at the present time. But it cannot be denied that in the future the transmission of spirochetes rendered resistant to organic arsenic and even mercury by long continued treatment of the syphilifer, may complicate the chemotherapy of the disease.

Just why the chemotherapy of paresis and tabes presents more difficulties than other types of visceral syphilis is difficult to state but is probably due to the parenchymatous position of the organisms. After all the same difficulties may exist under similar conditions in other of the internal organs, although evidences of our failure to improve or cure the lesions and symptoms are not as evident as in paresis and tabes, since the tissues or organs may be of lesser physiological importance than the brain and spinal cord.

In the treatment of rabbit syphilis I have so far found no evidence of variation in resistance to the curative activities of arsphenamin and neoarsphenamin among three different strains of *spirochæta pallida*, one of which was the original Nichols-Hough strain isolated in 1912 from the spinal fluid of a case of secondary syphilis developing a neurorecidive reaction after the injection of arsphenamin. Indeed, there is quite a uniformity of results among European and American investigations regarding the minimal curative doses of these compounds for syphilis of the rabbit (see Chapter XXIII). Doubtless the results are based upon work conducted with different strains. There is, therefore, absolutely no laboratory evidence today indicating that one strain of *Spirochæta pallida* is more difficult to destroy with arsphenamin and neoarsphenamin than other strains, except a strain in my laboratory which Klauder rendered slightly arsphenamin-fast or resistant by a series of transfers with the definite purpose of determining whether or not *Spirochæta pallida* could be rendered arsphenamin-resistant in the living animal.

Whether or not we accept the theory of plurality of strains of *Spirochæta pallida* or believe as I do that the whole question is one of variations in the inherent virulence and invasiveness, generalization and localization of organisms being influenced and modified by the degree of local reaction after infection and by predisposing tissue injuries and trauma, the lesson in relation to chemotherapy is plain. We must treat the disease as early as possible and in as energetic a manner as toxicological effects will permit. Furthermore we must insist upon a minimum amount of treatment for all cases regardless of clinical evidences of apparent cure and finally we must adopt rigid clinical serological and other criteria of cure. In other words, we must cure the syphilitic as rapidly as possible and we should advise and caution our patients regarding the probable influence of trauma and tissue injury as factors exerting some influence upon the subsequent localization of the parasites while their complete destruction is being attempted.

CHAPTER XXXVII

IMMUNITY IN SYPHILIS IN RELATION TO TREATMENT AND PROGNOSIS

The subject of immunity bears an important relation not only to syphilitic infection but likewise to the treatment and prognosis of the disease. This is especially true in relation to the mechanism of reinfection, superinfection and the cure of acquired and congenital syphilis.

Natural Immunity in Syphilis.—In the first place it may be stated that natural resistance or immunity to syphilitic infection probably does not exist among human beings. Numerous instances recorded in literature purporting to show the existence of individual immunity are more likely to be explained on the basis of accidental and fortuitous escape from infection due to intact epithelial barriers of the skin and mucous membranes or to the existence of a latent but unsuspected syphilitic infection. As will be shortly discussed, the presence of syphilis and even of extremely latent syphilis associated with otherwise good general health may apparently protect against superinfection and thereby explain what may otherwise be regarded as an example of natural immunity. Races, however, vary somewhat in susceptibility to syphilis; among those peoples in whom the disease is first introduced syphilis is frequently more virulent than usual. The Negro race also appears to possess a somewhat better defensive mechanism against *Spirochæta pallida* after infection has occurred.

Syphilis does not exist naturally among the lower animals. It must be stated, however, that venereal spirochetosis of rabbits bears a close resemblance to human syphilis and the causal organism *Spirochæta cuniculi*

resembles *Spirochæta pallida* very closely, but all inoculation tests of human volunteers with *Spirochæta cuniculi* conducted by Levaditi and Marie[1] have proven negative. Evidence at present indicates that *Spirochæta cuniculi* is a separate organism.

With the exception of rabbits and monkeys, the lower animals appear naturally immune to *Spirochæta pallida*, although a few investigators claim having successfully produced syphilitic keratitis in cats, dogs and sheep. My own attempts to produce syphilis in white rats, guinea-pigs and dogs by testicular inoculations with virulent strains of *Spirochæta pallida* from rabbit and human lesions have always failed. In my laboratory Klauder has endeavored to break down the resistance of rats and especially of the lymphocytes by preliminary exposure of the testicles to *x*-rays, but without success. The nature of this natural immunity is unknown. Weiss and Wilkes have found that *Spirochæta pallida* can be cultivated *in vitro* in the various tissues of the rat and guinea-pig and that the sera of these animals are almost devoid of antibodies for culture *Spirochæta pallida*. Normal unheated rat serum rarely agglutinates *Spirochæta pallida* in dilutions higher than 1:4 and guinea-pig serum seldom higher than 1:8 and both are apparently free of spirocheticidal substances. Normal rabbit serum may agglutinate as high as 1:20 but is almost free of spirocheticidal activity; these agglutinins, however, are not protective as shown by the ease with which the testicles of rabbits may be infected. There is something in the tissues of the rat, guinea-pig and other lower animals directly destructive to *Spirochæta pallida* although when these tissues are removed and emulsified under sterile conditions the organisms can survive and proliferate in the suspension of cells. Probably the wandering cells and more especially the lymphocytes are the protecting agents, although no evidences of phagocytosis were discovered in these experiments.

Among human beings the epithelium of the skin and mucous membranes together with the surface secretions appear to be the chief factors of resistance. As stated in Chapter XXXV, it is possible, however, that on mucous membranes at least, virulent strains of *Spriochæta pallida* may gain access to the interepithelial and subepithelial lymph spaces without a previous break in the layers of cells, since Reasoner has shown the infection of rabbits by application of spirochetes to the mucosa of the genital tract and Brown and Pearce, infection of the eyes of apparently normal rabbits by dropping the parasites into the conjunctival sacs.

Doubtless, however, there is an important relation between numbers and virulence of *Spirochæta pallida* and infection of human subjects. It is entirely likely that some individuals are actually invaded by *Spirochæta pallida*, but escape infection due to the destruction of the parasites by secretions or the body fluids although these defensive agents are feeble at best and probably ineffective in the presence of many highly invasive spirochetes. All of the surface tissues are susceptible and chancres have occurred on practically every portion of the skin and contiguous mucous membranes.

After infection has occurred, striking variations in individual resistance are easily apparent. As previously mentioned the negro appears to possess a better developed defensive mechanism although his escape from tertiary lesions may be explained on grounds other than the development of an actual immunity. The apparent escape from tertiary lesions and especially of the neuralaxis among races in the tropical countries is not now believed to be as frequent as hitherto thought, since more careful examinations have been employed. But pregnancy exerts a profound influence upon the course of syphilis in both mother and child, characterized by latency of the infection, which will be discussed shortly in more detail although it is not definitely

known at present whether latency under these conditions is due to some change in the life cycle of *Spirochæta pallida* or the development and operation of immunological agencies.

Acquired Immunity in Syphilis.—After syphilitic infection has occurred, the subsequent progress of the disease is combated by various defensive agencies. Small lymphocytes and plasma cells are quickly attracted to the foci of infection; likewise a few polymorphonuclear leukocytes and these, especially the small lymphocytes, probably produce antibodies against the spirochetes. It is also possible that plasma and cellular enzymes and especially lipases derived from the lymphocytes, exert some degree of antispirochetic activity.

It is highly probable that all or, at least most immunity principles, are produced right in and about the nests or foci of syphilitic infection. Some of these substances are then absorbed and distributed throughout the body and may effectually protect against superinfection. Nichols[2] in 1914 first showed that an active lesion in the testicle of a rabbit tended to inhibit the development of potential lesions in other parts of the body; Zinsser, Hopkins and McBurney[3] subsequently found that the resistance to superinfection was confined mostly to the infected tissues, that is, a syphilitic testicle of a rabbit could not be superinfected although the other testicle could be infected at the same or a later time.

Brown and Pearce have studied this local immunity with particular care and have shown experimentally in the rabbit that anything which reduces the local primary lesion actually tends to spread the infection. In other words, the primary lesions are looked upon as an expression of defense on the part of the infected host—a place where immunological agents are being produced which combat the spirochetes. Since *Spirochæta pallida* has already invaded the lymphatic glands of the rabbit within a few days of the time of inoculation, removal of the primary lesion by castration or its suppression by the administration of subcurative doses of arsphenamin has, in their experiments, generalized the infection. Apparently the immunological principles produced locally are absorbed and tend to protect other tissues and organs against spirochetic invasion. In the rabbit, this protection may be effective in the majority of instances except for the invasion of the lypmhatics nearest the testicular lesions which are invaded by the spirochetes before sufficient amounts of these immune principles have been produced. In the human being, these principles are probably but rarely sufficient effectually to prevent the progressive invasion of other tissues, but they doubtless exert some important influence in this direction.

It would appear, therefore, that the immunity principles of syphilis are produced mainly by the tissues in direct contact with the spirochetes. Very probably the lymphocytes are chiefly concerned in their production, but the fixed cells of the infected tissues may also participate in the process. This antibody-production occurs not only in the chancre but subsequently wherever spirochetes may locate—in the skin, heart, aorta, brain, etc. It is also probable, of course, that diffusible toxins from spirochetes are produced and absorbed that may prove antigenic for the usual antibody-producing tissues, which we regard, principally, as the bone marrow and the lymphoid tissues in general.

Rôle of Immunity in the Cure of Syphilis.—Unquestionably these immunity principles exert an important rôle upon the progress of syphilitic infection. It is possible that they may influence and control in a large part the distribution of spirochetes after the primary lesion and are doubtless important factors in the production of latency in syphilis. This immunity

appears to be developed more completely in some individuals than in others, and the negro is sometimes apparently more fortunate in this respect than others. Pregnancy likewise appears to aid in the production of these protective agencies.

Unfortunately, however, we do not know how to increase the production of these substances in human syphilitics for therapeutic purposes, but I am prepared to believe that the administration of vaccines of *Spirochæta pallida* may be of aid in this direction and even non-specific protein agents, as intramuscular injections of sterilized milk or some similar protein substance by intramuscular or intravenous injection. Off hand, one would surmise that the local primary lesion of syphilis should be left alone in order to obtain the maximum protection for the balance of the tissues and organs to be derived from the production of the immunity principles in this area, but these immunological agents are seldom if ever capable of curing syphilis and, since we now have in arsphenamin, neoarsphenamin and allied products substances capable of bringing about complete destruction of all spirochetes, the indications are to treat syphilis as soon as possible after infection. But the treatment should be energetic and sufficient. As shown by Brown and Pearce, subcurative doses in the rabbit may actually aid in spreading the disease and the lesson to be learned from their experiments is of tremendous importance in relation to the treatment of human syphilis and especially syphilis in the early stages. Fortunately in the majority of instances syphilitics in the clinical, primary and secondary stages are generally in good general health permitting the energetic administration of arsphenamin or neoarsphenamin and these should be administered as soon as possible and in adequate amounts.

Syphilis is not self curative, except possibly in exceptional instances. Even though its victims may be in apparent good health, it can usually be shown that the infection is only latent and that active lesions may be developed at later periods. In the aged and in those badly crippled with syphilitic or other chronic lesions reducing tolerance for antispirochetic remedies in adequate doses, it may be well not to disturb this latency and to leave well enough alone; but the immunity principles alone cannot be expected to cure human syphilitics and in the early stages, at least, the parasites should be attacked with vigor, as the complete cure of syphilis is dependent not upon the production of immunological agents but upon the administration of adequate amounts of antisyphilitic drugs.

Antibody-production in Syphilis.—What is the nature of the immunological principles produced mainly in the foci of syphilitic infection and probably in most part by the lymphocytes? Are they antibodies belonging to those already known in a general way in bacterial diseases as the antitoxins, opsonins, agglutinins and cytolysins?

The only serum antibodies so far discovered in syphilis are agglutinins and spirochetolysins. In 1913 I first discovered agglutinins for culture *Spirochæta pallida* in the sera of immunized rabbits and in human syphilitics,[4] and this discovery was soon confirmed by Nakano,[5] Kissmeyer[6] and by Broadwell, Matsunami and myself.[7] But Zinsser and Hopkins[8] have shown that agglutinin production for virulent spirochetes in rabbit and human lesions was much less than for avirulent cultures which reduced any significance to be placed upon the presence of agglutinins in the blood of human syphilitics in relation to immunity in this disease.

On the basis of investigations prior to 1911 with emulsions of tissues rich in spirochetes, Neisser and Bruck expressed the opinion that parasiticidal antibodies are not produced in the course of syphilis. Zinsser and Hopkins[9] have shown that the sera of rabbits and sheep immunized with a pure culture of *Spirochæta pallida* developed spirocheticidal antibodies for culture strains; but later Zinsser, Hopkins and McBurney[10] found that these antibodies had practically no action for virulent strains obtained directly from human

and rabbit lesions. Broadwell and myself[11] likewise found practically no demonstrable amounts of spirocheticidal substances in the fresh sera of syphilitics for a culture of *Spirochæta pallida*, but Noguchi[12] found that serum from a syphilitic rabbit destroyed culture spirochetes and more recently Eberson[13] has reported the presence of relatively large amounts of spirocheticidal substances in the sera of both syphilitic human beings and rabbits, especially in the latent stages. Eberson believes that these antibodies represent the immunological response in syphilis and are accountable for the periods of latency.

The substance responsible for the Wassermann reaction is probably also produced in most part by the lymphocytes in syphilitic exudates, as well as by the cells of the infected tissues. Klauder and myself[14] have found that secretions squeezed from primary human lesions may yield positive complement-fixation reactions many days before the blood Wassermann test yields positive reactions and our observations have been confirmed by Fuentes[15] and by Stern and Pypins.[16] The substance responsible for the Wassermann reaction, however, is not generally regarded as a true antibody and probably is not antispirocheticidal. Rather it is generally believed to be a reactionary product of the cells aptly designated by Neisser as "reagin," but its presence in the blood and spinal fluid does not run parallel with the evidences of immunity in syphilis. Eberson has observed that in latent and apparently cured cases of syphilis the Wassermann reaction may be negative when the serum is highly protective and spirocheticidal. It is commonly observed that the Wassermann reaction is strongest when the disease is most active and for these reasons the complement-fixation test conducted with the usual tissue extracts as antigens is not an indication of immunity but rather of infection. On the other hand, complement-fixation tests conducted with antigens of saline or watery extracts of *Spirochæta pallida* may be true antibody reactions, due to the presence of a *Spirochæta pallida* antibody different from the tissue "reagin" responsible for the Wassermann reaction as ordinarily conducted.

Whether or not opsonins are produced in syphilis cannot be definitely stated. In my laboratory the experiments conducted by Weiss and Wilkes have been largely of a negative character, although, owing to technical difficulties associated with opsonin experiments employing *Spirochæta pallida*, a definite opinion cannot be expressed. It is unusual to find spirochetes located intracellularly in sections of syphilitic tissue and in my opinion, phagocytosis plays but a minor rôle in resistance and immunity to syphilis.

As stated in Chapter XXXV, *Spirochæta pallida* may produce hemotoxins and other toxins in the tissues responsible for the anemia and general symptoms of syphilis, but so far no one has actually demonstrated their presence either *in vitro* or *in vivo;* neither has any one demonstrated antitoxins in the blood of normal or syphilitic human beings or the lower animals for these hypothetical toxins.

Antibody-production in syphilis, therefore, seldom if ever reaches a high degree. As previously stated, antibodies may be engendered in sufficient amounts to produce periods of latency during the course of syphilis and may even protect some organs against invasion with *Spirochæta pallida*, as expressed by Keidel[17] in reference to the apparent escape of some syphilitic individuals from infection of the tissues of the central nervous system, but they are not produced in sufficient amounts effectually to render syphilis a self-limited or self-curative disease or effectually to protect against reinfection after the cure of syphilis. Whether or not the immunity principles engendered in the local lesions and responsible for the resistance of these to superinfection are agglutinins and spirochetocidins as found in the blood, cannot be definitely stated, but very probably this local resistance engendered in the foci of syphilitic infection are antibodies of these kinds.

Nature of Latency in Syphilis.—Latency in syphilis is one of the most remarkable phases of the disease. This does not refer to the so-called primary latent period between the healing of the chancre and the outbreak of the skin and mucous membrane lesions, during which time the parasites have been or are being deposited in the tissues with the development of lesions which represent local defensive reactions in exactly the same manner

as the chancre is a defensive reaction, but rather the latency of the later stages of the disease.

Is latency due to a reduction in the virulence of *Spirochæta pallida?* Is it a manifestation of an unknown phase in the life cycle of the parasite, or is it a neutralization in whole or part of its pathogenic agencies by the antibodies discussed above? In all probability latency is due to a combination of reduction in virulence of the spirochetes associated with a neutralization of their pathogenic activities by cellular or humoral antibodies, since definite evidence of changes in the life cycle of the parasite has not been produced. But very probably antibodies are more important in this relation than reduction in virulence, because anything depressing tissue immunity and resistance like trauma favors renewed activity of the spirochetes and, as shown by Brown and Pearce,[18] the administration of subcurative doses of arsphenamin and neoarsphenamin to rabbits may so depress immunity principles in local lesions as to render these susceptible to superinfection even though the tissues still harbor living spirochetes. Furthermore we know that the administration of arsphenamin, neoarsphenamin and mercury is sometimes followed by an exacerbation of the disease with the production of a Wassermann reaction (the provocative reaction) which I interpret as the result of a depression of immunity and local resistance followed by spirochetic activity rather than an increase of virulence of the spirochetes.

Antibodies probably reduce the invasiveness of the spirochetes in the tissues and neutralize those substances responsible for the chemotaxis of lymphocytes explaining the presence of the organisms in the heart muscle and other tissues without lymphocytic and plasma cell infiltrations as described by Warthin. But the spirochetes are not dead and possess potential pathogenic powers capable of action when the restraining influences are removed. However, there is probably a true reduction in their virulence in addition to a constant neutralization of their pathogenic agencies brought about by the effects of these antibodies.

In addition it is highly probable that tissue changes and especially the production of fibrous tissue play some part in the production of latency. In large lesions of the gummatous type the fibrous tissue and especially the vascular sclerosis tend to reduce and cut off nutrition leading eventually to tissue necrosis and the death of spirochetes. Walls of lymphocytes and plasma cells and especially of fibrous tissue may just as effectually prevent the local spread of infection or the entrace of spirochetes into lymphatic and vascular channels as in tuberculosis and prove factors of considerable importance in the production of latency and self limited distribution of syphilitic lesions.

Limitation of Latency in Syphilis.—After immunity has been acquired sufficient for the production of latency of varying degrees and duration, why may the disease spring into renewed activity at later times? Why is not the immunity lasting and sufficient for maintaining a fair degree of good health for an indefinite period?

In the first place, it is possible that the spirochetes gradually acquire a "fastness" or resistance to the antibodies just as we definitely know that bacteria may acquire a resistance to serum antibodies. If such occurs in syphilis it is readily understood that in time a race of spirochetes will be produced in the patient which are no longer held in check by the immunity principles but which proceed with the invasion and infection of new tissues and organs.

Furthermore, there can be no doubt that tissues injured by trauma are less able to resist invasion by the spirochetes than normal tissues and, under

these circumstances, spirochetes which have had their virulence reduced by antibodies are still capable of infecting these local areas of reduced vitality and resistance.

It may be that the immunity is gradually reduced in the long periods of latency if the degree of antibody-production is in ratio to the degree of spirochetic activity. Finally a point may be reached at which the antibodies are greatly reduced but without complete eradication of the parasites and, the balance between the two now being disturbed in favor of the latter, the surviving spirochetes may spring into renewed activity as the result of the administration of drugs, an intercurrent infection or some kind of tissue injury and proceed with the invasion and infection of new tissues with little or no restraint. This may be and usually is followed by renewed antibody-production, the cycle of latency and renewed activity of the infection being repeated sometimes many times during the lifetime of the syphilitic subject.

Influence of Pregnancy upon Syphilitic Infection.—In connection with this discussion of immunity in syphilis and especially in relation to the nature of latency, the influence of pregnancy upon the course of syphilis is deserving of special attention. It is a common and well established clinical experience that syphilitic mothers develop extreme and oftentimes prolonged periods of latency during which time a positive Wassermann reaction may be the only sign of infection. Likewise, pregnancy appears to reduce the incidence of neurosyphilis as compared with its incidence among men and childless women. Furthermore, this latency is sometimes transmissible to the child in the uterus, because in congenital syphilis the lesions and symptoms of the disease may not become clinically apparent for many years after birth.

Brown and Pearce[19] have shown very clearly that the reaction of the rabbit to a genital inoculation with *Spirochæta pallida* practically coinciding with conception differs very decidedly from that of the normal animal inoculated in the same way and that this difference extends through the period of pregnancy and well into the period of lactation. The differences noted were of two kinds: ordinarily, it appeared that the defensive mechanism of the pregnant animal was capable of opposing a resistance to inoculations performed at the time of conception such that little or no clinical signs of infection appeared—a condition possibly analogous to that upon which Colles' law was founded. In other instances, however, slight local lesions and marked constitutional disturbances were produced which suggested an ineffectual resistance to the infection or a breaking down of the defensive mechanism.

Gartner[20] has recently stated that on the basis of the incidence of paresis over a period of years in a population of about 38,000,000 Germans, the ratio of paretic men to women was 3.43:1 and suggests, in common with the opinions of Fournier and others, that this difference is largely due to the higher incidence of syphilis in men than in women, together with the greater chances for tissue injuries and such predisposing factors among men. But Moore[21] has recently shown that in Baltimore clinical neurosyphilis is about three times as frequent in men as in women and that, while the nervous systems of the two sexes are invaded with equal frequency in the early stages of syphilis, as shown by the relative percentages of spinal fluid abnormalities, the course of syphilis is markedly altered by the simultaneous occurrence of pregnancy and that pregnancy is the most important point of difference in the ordinary life history of the two sexes and an important factor in altering the course of syphilis in the woman. Indeed, if it were not for the danger of transmitting the disease to offspring, one could conclude from these laboratory and clinical studies that pregnancy is a therapeutic measure of con-

siderable value, insofar, at least, as concerns the production of latency and the limitation of dissemination of infection.

Just how pregnancy influences syphilitic infection is unknown. Are changes induced in the life cycle of the spirochetes? There is no morphological evidence of such in animal experiments and the examination of syphilitic placentas and fetuses. Is antibody-production increased in the mother? If so, are the antibody producing tissues stimulated by metabolic changes coincident with pregnancy and lactation? Are antibodies produced in the placenta and possibly in the fetus which are transmissible to the mother and reenforce her antibody mechanism? Very probably changes in the syncytial and placental tissues of this kind are the chief factors. The evidence at hand indicates that the mother is less extensively infected than is general in males and in non-pregnant females, and for this reason there is no reason for believing that antibody-production in the pregnant individual is greater than usual if we accept that antibody-production primarily occurs in syphilitic foci and, therefore, is roughly parallel with the degree of dissemination of the spirochetes and the number and size of syphilitic lesions. Rather it would appear that the enhanced immunity of the pregnant subject is due to a re-enforcement and, if such is true, one naturally suspects that the new tissues of pregnancy are actively concerned in the process, since it has been shown that they are frequently infected. On the other hand pregnancy and lactation may increase the invasiveness, virulence and general pathogenic properties of the spirochetes suggesting that the immunity mechanism may be depressed by some accident. Either the influence of pregnancy is exerted through the medium of an influence upon antibody-production or through some other agencies connected with the pregnant state and operative very early in pregnancy which influence the pathogenicity of *Spirochæta pallida* and generally in the direction of a reduction of these properties.

Laws of Colles and Profaeta in Relation to Immunity in Syphilis.—Colles believed that the apparently healthy mother of a syphilitic child escaped infection by reason of acquiring an immunity during pregnancy and that she could nurse the child without danger of infection. Profaeta believed that the apparently healthy child of a syphilitic mother likewise acquired an immunity and that there was little or no danger of it contracting syphilis from the mother. We now know, however, that the mother in the first instance and the child in the second are frequently infected with syphilis in extreme degrees of latency, a positive Wassermann reaction being the only sign of infection.

Doubtless the latency of syphilis in both mother and child is due to the influence of pregnancy as discussed above. As previously stated, the nature and mechanism of this reduction in the virulence and activity of *Spirochæta pallida* associated with pregnancy are unknown, but it apparently is associated with an increased antibody-production which gradually reduces the virulence of the parasites and restrains the production of new lesions and the progression of old ones. Whether pregnancy stimulates the antibody-producing tissues or the increase of antibodies is due to their production in the new tissues of pregnancy, cannot be stated, although in my opinion the latter is the more probable mechanism.

At any rate, the apparently healthy mother of a frankly syphilitic child is to be regarded as a subject of latent syphilis and the latency may be so extreme that even the Wassermann reaction may be consistently negative for long periods of time. Personally I cannot believe that it is generally possible for a woman to give birth to a syphilitic child and escape infection and I believe she is a fit subject for treatment. Her disease is latent and may remain so for many years but tertiary lesions are apt finally to develop.

Whether the child of a syphilitic woman is always syphilitic is much less certain. For example, the mother may have been infected during the last few weeks of pregnancy and it is possible under these circumstances that the child may be born before infection occurs by way of the blood stream. Furthermore, I believe it is possible for a child conceived and born during the latent stages of infection of the mother to escape infection because it is always possible that during the entire period of pregnancy the lesions in the mother may be so latent that spirochetemia does not occur and it is apparent that the child in the uterus can be infected only by way of the maternal blood. Certainly the most rigid clinical and serological examinations of the children of syphilitic women frequently fail to elicit the slightest evidence of syphilis, although it is to be admitted that one cannot be absolutely sure of freedom from infection, as it is well known that the disease of the child may be so latent that lesions do not develop until very late in childhood and, indeed, not until adult age has been reached. From the standpoint of treatment, I believe that every child of a woman presenting active lesions of syphilis during pregnancy or, in the absence of these, a persistently positive Wassermann reaction, should be regarded as syphilitic and treated as such for a time at least despite negative evidence of infection. If the child is born during the late years of syphilis in the mother, when the latter shows no clinical evidences of the disease and yields persistently negative Wassermann reactions, I believe that one may safely conclude that the child does not require treatment if it is in good general health; it is possible however, that extremely latent infection may be present under these circumstances and especially if it is the first child.

Superinfection and Reinfection in Syphilis in Relation to Immunity and Cure.—By *superinfection* in syphilis is meant the successful reinoculation and infection of a human being or lower animal already syphilitic; this added infection may be with spirochetes from the syphilitic's own pre-existing lesion or lesions, in which case it is called *auto-inoculation*, or, by spirochetes derived from the lesions of some other person or lower animal. By *reinfection* is meant the production of a brand new attack of the disease after the preceding syphilitic infection has been presumably completely cured and eradicated. The difference in meaning of the two terms is dependent, therefore, upon whether syphilis is curable and if so, whether the completely cured syphilitic is vulnerable to a new infection with *Spirochæta pallida*. Regarding the cure of syphilis there are decided differences of opinion which will be later reviewed; likewise different opinions are held regarding the questions of superinfection and reinfection in syphilis, although we now have sufficient data on superinfection to discuss the question with considerable accuracy without prominently bringing up the question of curability.

As soon as *Spirochæta pallida* has gained access to the interepithelial and deeper lymph spaces and begun to bring about tissue changes, infection has occurred even though there may be no visible evidences of the occurrence. From this time on until the chancre is apparent, superinfection is readily possible. After the chancre is well developed, superinfection is still possible for a matter of a few days but rarely for more than three weeks; the superinfection may be caused by spirochetes from the chancre and producing other chancres in the immediate vicinity called autoinoculation which occurs in 20 to 30 per cent. of primary syphilis in men, or, the superinfections may be chancres of the finger, lips, anus, etc. During the clinical secondary stage superinfection practically never occurs either accidentally or by experimental inoculation insofar as can be determined clinically; it is possible, however, that superinfection may occur at this time but without the production of a

chancre, the lesion at the site of inoculation being only a papule, as maintained by Finger and Landsteiner,[22] or, indeed, possibly without any discernible local changes at all at the point of inoculation. During the latent and tertiary stages superinfection is only occasionally successful, if the criterion of success is taken as the development of a chancre; here again Finger and Landsteiner claim that superinfection is more frequently successful than surmised, but that the local lesion does not resemble a chancre but an ulcerating tertiary type of lesion similar to those presented by the patient.

This resistance to superinfection developing early in the primary stage, reaching the acme during the secondary stage and diminishing during the latent and tertiary stages, is ascribed to the influence of immunity and, as stated by Neisser, only syphilitics possess this immunity or resistance to infection with *Spirochæta pallida*. There can be no doubt that it exists and there are no valid reasons for disputing the rôle of acquired immunity as the mechanism concerned, but whether this immunity is as absolute or as frequent as current opinions indicate is much less certain. John[23] has collected quite a large series of cases from the literature of apparently successful superinfections, although some of these may have been true reinfections of cured syphilitics. According to Levaditi and Marie[24] infection with a so-called dermotropic strain of *Spirochæta pallida* does not immunize against a neurotropic strain, and the reverse; if this is true it must be that Finger and Landsteiner are correct in their belief that superinfection is more common than indicated by clinical observations. If, on the other hand, superinfection is as rare as commonly supposed after the primary stage of syphilis, this immunity is to be accepted as evidence of the unity of the *Spirochæta pallida* unless Levaditi and Marie are in error in their statement that one strain does not immunize against the other.

Naturally one wonders why a syphilitic is susceptible to extensions and exacerbations of his own infection while apparently immune to superinfection with spirochetes introduced from without. If there is but one *Spirochæta pallida*, although different strains of this one parasite of varying virulence, why should acquired immunity principles be sufficient for protecting against superinfection and yet insufficient for preventing the infection of new tissues by the spirochetes in the body? It may be a question involving numbers of spirochetes in that the immunity is sufficient for protection against the relatively few organisms applied from without while inefficient against the many that are within. Or it may be, as I personally believe, that the spirochetes within have acquired a "fastness" or resistance to these antibodies as they may to drugs, and for this reason are not as readily and effectually controlled or destroyed as spirochetes introduced from without. Finally, it may be in part a quantitative reaction in that during the latent stages superinfection does not occur because the antibodies are at a maximum, whereas during the less latent or mildly active periods in the later stages of the disease superinfection is possible but without the development as a chancre, since the local primary lesion of the superinfection is modified by the antibodies already present in the body fluids.

Does true reinfection occur in human syphilis? That is, may an individual recover from syphilis with complete eradication of all spirochetes from his tissues and then contract a new infection? In the first place, it is of course impossible at the present time to be absolutely certain of the cure of syphilis of human beings in the sense of complete eradication of all parasites from the tissues, but I know that rabbits with testicular lesions can be absolutely cured with arsphenamin and neoarsphenamin and that after a relapse of two to six weeks may be successfully reinfected. Human beings known to have

syphilis have undoubtedly contracted true second attacks of the disease after the treatment of the first; an increasing number of such cases are being reported in which it is certain that the new chancres are not recurrent chancres (chancre redux) or tertiary lesions. But are such cases to be accepted as evidence that the first syphilitic infection was completely eradicated or, are they in some instances at least, merely superinfection, that is, brand new infections grafted on to the preceding one and contracted because the immunity was insufficient to afford protection?

For example, Lipschutz,[25] in 1917, was able to collect 357 cases of apparent reinfection recorded in the literature, but since the majority were reported before our modern methods of diagnosis and treatment, it is questionable whether all were true cases of reinfection. But more recently White,[26] Schweitzer,[27] Schamberg,[28] Klauder,[29] Bechet,[30] Williams,[31] Thibierge,[32] Boas,[33] Reasoner,[34] Driver[35] and others have reported cases conforming more nearly to the conditions laid down by Driver.

It is commonly stated that a new infection occurring in an individual known to have had syphilis is a sure sign of the complete cure of the disease. But it is not now permissible to accept this dictum. Brown and Pearce,[36] for example, have shown that syphilitic rabbits treated with subcurative doses of arsphenamin and neoarsphenamin may still be reinfected or rather superinfected and I have been able to confirm their results; indeed, subcurative doses of arsphenamin and neoarsphenamin sometimes increases the susceptibility of these syphilitic animals to superinfection.

In other words, the question of reinfection and superinfection in syphilis is, as stated by Jacobi,[37] one of immunity and not of cure. Syphilitic individuals may escape superinfection not only because they harbor spirochetes in their tissues, but because they possess a sufficient degree of acquired immunity. Individuals contracting a true second attack of syphilis cannot be assured that they have been completely cured of the first attack, but only that the first attack did not leave them immune to the disease.

Unquestionably, however, the development of a true second attack of syphilis can be accepted as evidence that the first attack *may* have been completely cured or, at least, that but relatively few spirochetes were left in the tissues, because when there are many active spirochetes in the tissues the immunity is usually sufficient to apparently protect against superinfection. Unfortunately, the immunity does not last long after a great reduction or complete eradication of the infection has been effected by treatment; in some instances the immunity has passed away sufficiently to permit reinfection or superinfection within eight months after the cessation of treatment.

Influence of Chemotherapy upon Immunity and Antibody-production in Syphilis.—As stated in Chapter XXIII there is little or no evidence to support the hypothesis that arsphenamin, neoarsphenamin and allied compounds increase antibody-production and immunity in syphilis and that a part of their curative properties are due to these effects. As stated in that chapter, there is no direct evidence to show that arsphenamin, neoarsphenamin and allied products, mercury and bismuth, which are spirocheticidal, possess any stimulating effects upon the antibody-producing tissues; if they have any direct or indirect effects at all in this direction it is only by first acting upon the spirochetes and thereby liberating antigenic products which stimulate antibody production.

Drugs cannot be said, therefore, to increase immunity in syphilis. Indeed, the reverse may occur. Brown and Pearce have found, for example, that rabbits inoculated intratesticularly and treated with subcurative doses of arsphenamin and neoarsphenamin, when the first cycle of the reactions were

nearing their acme, were highly susceptible to a second inoculation and, although not cured of their original infection, reacted to the second inoculation with the formation of lesions indistinguishable from those of the first infection; also that *in certain instances the treatment given had rendered infected animals more susceptible to infection than the normal controls.*

It would appear, therefore, that chemotherapy with arsphenamin and neoarsphenamin, at least, may actually lower immunity to syphilis instead of increasing it and the influence of these drugs upon immunity in syphilis is of great importance because the experiments of Brown and Pearce indicate that undertreatment of syphilis is perhaps almost as serious as no treatment at all, and that a few doses of arsphenamin or neoarsphenamin may give little more than a false sense of security.

Immunity in Syphilis in Relation to Prognosis.—Naturally a most important question to the syphilitic and one that he seldom fails to discuss repeatedly with the physician is the prognosis of his disease. The subject cannot be briefly dismissed and requires consideration from several different angles which are discussed in Chapter LXXIX, but here may be summarized the influence exerted by immunological factors upon this important question.

Except in rare instances, syphilis does not appear to be a self-limited or self-curing disease. Antibodies and tissue immunity are produced, but these are seldom if ever sufficient for bringing about a complete eradication of the organisms from the tissues unaided by drugs. Sometimes the physician encounters individuals who, deluded by a false sense of security by reason of latency of the syphilitic infection and good general health, believe that exercise and other hygienic measures will be alone sufficient for effecting a cure; doubtless these are aids but we have no reason at all for believing that the immunological and other natural defensive agencies of the body are able to permanently hold syphilis in check and ultimately bring about cure unaided by adequate and judicious drug treatment.

Acquired immunity in syphilis is, however, an important factor in relation to the progress of the disease and tends to limit and prevent the invasion and infection of new tissues and organs and to prevent the progressive growth of old lesions. Immunity is mostly responsible for the latency of the disease and, if syphilis is uncurable when treatment is begun in the late stages, long periods of latency are next best, and insofar as duration of life and usefulness are concerned, may practically amount to a cure in the clinical if not in the pathological sense. In some individuals immunity is apparently acquired more promptly and effectually than in others and pregnancy is especially favorable to the acquisition of immunity in both mother and child.

The acquired immunity of syphilis generally protects against superinfection after the primary stage of the disease, although this protection is not absolute and when the numbers and pathogenicity of the *Spirochæta pallida* have been greatly reduced and especially by drugs, superinfection may occur and be possibly mistaken for the true reinfection of a cured case of syphilis. Inadequate drug treatment may likewise apparently reduce immunity to superinfection and for this reason chemotherapy bears an important relation to the immunity and prognosis of syphilis.

The acquired immunity of syphilis is of short duration and rapidly disappears after the complete cure of the disease; apparently the immunity is in large part a tissue immunity participated in by the tissues in direct contact with the spirochetes and likely to rapidly diminish with reduction in the numbers and pathogenicity of the parasites.

Immunity in syphilis influences the prognosis, therefore, largely by the rôle it plays in the production of latency, even though it is insufficient for

bringing about a spontaneous cure of the disease. Chemotherapy bears an important relation to this immunity and to prognosis, because, while adequate treatment may cure the disease, in a clinical sense, at least, inadequate treatment may reduce the immunity and fail to cure, yielding only temporary beneficial results and a false sense of security.

CHAPTER XXXVIII

PATHOLOGY OF SYPHILIS IN RELATION TO TREATMENT AND PROGNOSIS

The question of the curability of syphilis is greatly influenced by the duration of the disease and the pathological changes produced before treatment is instituted as well as the kind and amount of treatment given, and it is my purpose in this chapter to discuss the question of treatment as influenced and modified by the pathological changes produced.

Clinical versus Pathological Stages of Syphilis.—Ricord's famous classification of syphilis into the *primary stage*, embracing the chancre and adeno-

pathy, the *secondary stage*, embracing the early cutaneous and mucous membrane lesions, and the *tertiary stage*, embracing the late fibrotic (gummatous) lesions of any tissue or organ, may still be of some service for the clinical and chronological classification of the lesions and symptoms of syphilis, but it is being gradually abandoned and is entirely inadequate from the viewpoint of pathology. Fournier's fourth or *quaternary stage*, embracing tabes dorsalis and paresis, is surely obsolete and the term *latent stage* is only of clinical sense. From the standpoint of pathology it is probable that true latent syphilis is uncommon, as the spirochetes are seldom entirely inactive but are producing lesions which, on account of small size or location, may not show symptoms and thus readily escape detection. Theoretically, at least, syphilis always demands treatment, regardless of its apparent latency and harmlessness; practically, however, treatment is not always indicated and especially if active and vigorous therapeutic measures are contraindicated by senile or advanced pathological changes in a vital organ or organs.

From the standpoint of the pathologist and chemotherapeutist, the disease is better divided into *early and late syphilis*. These terms, however, are not strictly synonymous with acute and chronic. There is probably no such thing as pure chronic syphilis as a disease from the pathological standpoint; the disease may be chronic from the standpoint of symptoms and a particular lesion may be chronic in the sense that it is fibrotic, but the same organ or tissue may show early or acute lesions alongside of the old or chronic. In other words, from the standpoint of pathology and treatment, the terms "acute" and "chronic" should be applied only to the state of a particular lesion or lesions; they are not always applicable to the disease as a whole, because a late case of syphilis may, indeed, present very acute and dangerous lesions which are fresh lesions and not merely the exacerbation of old or chronic ones.

In other words, the pathologist classifies syphilis according to the histological condition of the lesions and this classification is likewise of most value to the chemotherapeutist. The stage of early syphilis is one in which none of the lesions are fibrotic and in which vascular occlusion has not occurred; hence, chemotherapy may effectually destroy all of the spirochetes. The stage of late syphilis embraces the clinical tertiary stage in which many of the lesions are fibrotic and probably beyond the possibility of cure in the sense of destruction of the parasites and absorption of the inflammatory tissue; on the other hand, however, younger lesions may likewise develop at this time and these are vulnerable to therapeutic measures before advanced fibrosis and endarteritis have occurred.

General Pathology of Syphilis.—It is not my purpose to review here in detail the gross and microscopical pathological changes of syphilis; excellent descriptions are to be found in text-books of pathology and systematic works on syphilis. After all the pathology is relatively simple and the processes essentially similar in all organs. What occurs at the site of primary inoculation is practically duplicated wherever the spirochetes may locate, except that secondary bacterial infection does not occur as it may in a chancre, unless the lesions are located in the skin or a mucous membrane. Even in the skin the development of suppurative lesions (malignant syphilis) is influenced by the state of the patient's natural immunity or resistance to staphylococci and streptococci as well as to a lesser extent by the virulence of the spirochetes.

Briefly, these changes consist of a deposition of the spirochetes in lymph spaces; in the primary lesion or chancre this usually means the interepithelial lymph spaces of the skin or a mucous membrane, followed by invasion of

the lymph spaces of the corium. From these locations the parasites are swept into lymph channels, the lymph glands and finally the venous blood. In the smallest venules they may escape into the perivascular lymph spaces, but probably are mostly conveyed to the heart, pass the capillaries of the lungs and enter the arterial blood, by which they are widely distributed and locating by preference in the perivascular lymph spaces of the smallest arterioles in different organs and about the vasa vasorum of the large arteries themselves. What governs the distribution of the spirochetes cannot be stated; some organs usually escape while others are usually invaded. The skin and mucous membranes, the aorta and heart, testicles, brain and spinal cord are the usual seats of localization. Whether invasion is controlled by physical factors, by previous injury with consequent decrease of resistance or by inherent biologic qualities of the spirochetes, are questions which have already been discussed in the preceding chapter.

The resulting defensive reaction of the host (organ or tissue invaded) is usually tardy. This is probably due to the fact that numerically the infection is not heavy; only a few spirochetes are deposited and their presence may easily escape prolonged microscopical examination of the tissues. Furthermore, they tend to proliferate slowly. The deposition of a few virulent staphylococci or streptococci in the deeper tissues may be followed in three days or less by a well-defined macroscopic lesion, but *Spirochæta pallida* apparently requires two to four weeks before a local lesion of macroscopic size becomes apparent although microscopically a lesion may be detected after a few days.

The offensive mechanism on the part of the spirochetes probably consists in the production of a toxin which devitalizes and finally destroys the cells in closest contact and especially nerve and heart cells. It may be that this destructive substance is not a true toxin; at least no one has yet demonstrated *in vitro* a toxin for *Spirochæta pallida*, but it is apparently a toxic substance of unknown quality or a substance or process impairing the nutrition and metabolism of the neighboring cells. The defensive mechanism consists in throwing about the spirochetes a wall of lymphocytes and plasma cells followed later by fibrous tissue. If the spirochetes are not offensive, that is, are in a state of extreme latency or if their toxic or other offensive agencies are being neutralized by the body fluids and cells, positive chemotaxis and walling off may not occur, as indicated by the observations of Warthin,[1] who found spirochetes in the heart muscle and elsewhere without this admiring circle of lymphocytes and fibrous tissue.

However, walling off with lymphocytes, plasma cells and fibrous tissue is the usual procedure, but the whole focus may be so small as to escape naked eye inspection. For this reason Warthin objects and rightly so, to excluding a diagnosis of syphilis on the basis of no clinical lesions or symptoms, negative Wassermann reactions and the absence of macroscopical lesions at necropsy. Indeed, his work has shown that the questions of the true incidence of syphilis, the exact sensitiveness and value of the complement-fixation and other diagnostic reactions and the exact status of chemotherapy must await further microscopical studies of the organs and especially of the heart, aorta, testicles, pancreas and adrenals of many human subjects, including not only those known to have had syphilis during life but many as well who presumably did not.

Pathologists have long known in a general way that syphilitic lesions may be of microscopic size but Warthin has shown in a particularly clear and convincing manner that such lesions may be present when macroscopic lesions are not found at necropsy. A mistake pathologists have been making here-

tofore has been to depend upon finding lesions of macroscopic size and if such were not found at the necropsy table to state that syphilis was not present. To Warthin belongs the credit for showing the error of this practice; we cannot be sure that an organ or tissue is free of syphilis until it is examined microscopically if not for *Spirochæta pallida*, at least for the histological changes of perivascular round and plasma cell infiltration with vascular changes. One drawback, however, is the danger of interpreting all such areas as syphilitic. I am sure such is not the case as similar changes may occur in other chronic infections and, indeed, as a result of the administration of mercury and arsphenamin. For this reason I believe Warthin's incidence of 30 to 40 per cent. syphilis among his series of examinations may be too high, but it is hoped that under the stimulus of his work that the pathological histology of syphilis will receive more study and probably result in discovering histological changes as surely pathognomonic as the presence of the spirochetes themselves.

In time *Spirochæta pallida* may invade in this manner practically any tissue of the body. The resulting lesions may be small and scattered and even diffuse or localized. When fibrosis is well advanced and of macroscopic size the local lesion is designated as a gumma. But very few spirochetes survive in these gummas although they may be found at the periphery, sometimes forming new and acute lesions analogous to the daughter tubercles about a large tuberculous lesion.

As previously stated, *Spirochæta pallida* is especially found in perivascular lymph spaces and in the media and adventitia of the larger vessels. The resulting lymphocytic and plasma cell infiltration followed by fibrosis naturally leads to the production of a chronic arteritis which may so thicken the walls as to encroach on the lumen and result in obliteration (arteritis obliterans). In gummas this may result in cutting off blood supply with consequent caseation and liquefaction necrosis brought about by the digestive activities of the cellular proteases from the dead cells. If an iodid is being administered at this time, the process of softening is hastened probably because the iodin neutralizes the restraining influence of the antiferment, regarded by Jobling and Petersen, as the unsaturated fatty acids of the plasma.

As previously stated, the cells of the organ invaded by *Spirochæta pallida* naturally suffer to some extent. If the parasites are of greatly reduced virulence they may do very little apparent damage and are surrounded by but few lymphocytes. As a usual rule, however, local destruction of cells occurs and especially when the spirochetes locate in the heart, brain, spinal cord and pancreas. This destruction is probably primarily due to toxic substances emanating from the spirochetes; later the fibrous tissue about the focus and especially that in the walls of the blood vessels still further reduces nutrition which may eventually end in complete destruction of these cells. Depending upon the location and size of the lesion and the number of physiologically important cells involved, symptoms are produced. Located in the posterior columns of the spiral cord, for example, the lesion need not be large or involve many of the nerve fibres before its presence is made known.

Such in brief is the general pathology of syphilis, the essential processes being similar wherever spirochetes may locate. In the untreated and uncured syphilitic new lesions are probably being constantly produced, so that the early and late lesions coexist together. From the standpoint of pathology and chemotherapy we have but two kinds of lesions—the early or pre-fibrotic and the late or fibrotic lesion. Of course, every recent case of syphilis embracing the primary and secondary clinical stages of Ricord are

early cases from these standpoints, but Ricord's latent and tertiary stages refer to clinical symptoms and time only because from the standpoint of pathology and chemotherapy spirochetes are probably never entirely quiescent and in the co-called tertiary stage truly early lesions and symptoms may develop.

Difficulties of Diagnosis and the Incidence of Syphilis.—Syphilis may manifest itself clinically in a great many different lesions and especially in the late stages of the disease. Any tissue or organ may become involved and for this reason the disease concerns every specialty in the practice of medicine and surgery. No one physician can really hope to become sufficiently skilled in detecting the lesions of the disease in all cases because its diagnosis requires too much special knowledge. For example, the dermatologist may be best able to detect the skin and mucous membrane lesions, the opthalmologist the eye lesions, the neurologist and psychiatrist the brain and spinal lesions, etc., but syphilis belongs to no one specialty in medicine since it belongs to all and after the primary and secondary clinical stages have passed, may readily enough escape diagnosis by even the most skillful physician and surgeon. During the clinically latent stages and especially in congenital and maternal syphilis, these difficulties are of course greatly multiplied. Any statistics, therefore, based upon the clinical diagnosis of syphilis for expressing the incidence of the disease are apt to be too low, because the error of failing to detect syphilis clinically is greater than the chances of error of making false positive diagnoses.

Incidence based upon histories are even more misleading, not only because many persons purposely deny all knowledge of infection, but because many honestly do not know that they have become infected. This is especially true of congenital syphilis and of acquired syphilis of women.

The Wassermann reaction has greatly aided in the diagnosis of the disease and especially in its late and latent stages. This question is discussed in more detail in Chapter XXXIX because of its practical importance and value, but here it may be stated that with present-day technic even the most sensitive methods fail to detect all cases and especially cases of latent maternal and congenital syphilis. The so-called antibody or "reagin" in the blood and spinal fluid responsible for the reaction is apparently produced by the lymphocytes and other cells about the foci of spirochetic infection, and in latent syphilis the organisms may possess so little virulence that the degree of antigenic stimulation is at a minimum, with the result that sufficient amounts of this antibody are not produced to yield positive complement-fixation reactions. The error, therefore, is apt to be on the negative side, but I believe that a sensitive and acceptable complement-fixation test is at present the best single means for the detection of syphilis after the chancre stage. The percentage of negative errors cannot be accurately stated, but it is my impression that in active syphilis—that is, in cases of syphilis of any stage showing active lesions—the percentage of negative errors is less than 5 per cent. Tabes dorsalis, however, is an exception; in this syphilitic disease the active lesions may be large enough to produce marked symptoms because of their location, but too small to produce sufficient amounts of "reagin" in the blood and spinal fluid to yield true positive reactions in about 10 per cent. of cases. In other words, the clinical symptoms of syphilis depend primarily upon the location of the lesions and secondarily upon their size; positive Wassermann reactions, however, depend primarily upon the size, activity and degree of involvement of the lesions irrespective of their location.

Incidence based upon macroscopic necropsy findings is likewise in error on the negative side. The chronic lesions of syphilis of many of the internal

organs are sufficiently distinctive to permit naked eye detection by skillful pathologists, but small lesions are readily overlooked and lesions of microscopic size of course cannot be detected unless the tissues are thoroughly examined microscopically. Symmers[2] found *gross* anatomic evidence of syphilis in 314 cases out of 4880 necropsies performed at Bellevue Hospital in New York City; this is 6.5 per cent. Warthin believes that he found microscopical evidences of syphilis in 300 out of 750 necropsies performed at Ann Arbor, or 40 per cent. Symmers based his findings upon the presence or absence of lesions of macroscopic size, while Warthin based his upon the prolonged and painstaking microscopical examination of the tissues for the diffuse and localized lesions of syphilis and for the spirochetes. Warthin has emphasized, therefore, that the absence of syphilis in a cadaver cannot be based upon failure to find macroscopic lesions, but that the tissues and especially the heart, aorta, testes, pancreas and adrenals must be examined microscopically.

However, the diagnosis of syphilis by histological examination of the tissues is likewise subject to error, since the histological changes produced by *Spirochæta pallida* are not pathognomonic. Perivascular round-cell infiltration with fibrosis of the media and adventitia of blood vessels are the most constant histological changes, but similar changes are found in other chronic infections. Indeed, as found by Lucke and myself[3] in the histological examination of the tissues of rats and rabbits treated with arsphenamin, neoarsphenamin and mercury, it is possible that these compounds may produce focal areas of round-cell infiltration in the brain, heart, etc., that may be mistaken for areas of spirochetic invasion if encountered in human tissues. Of course the finding of spirochetes in the tissues may be accepted in this country as pathognomonic, since invasion during life or after death with saprophytic spirochetes is not known to occur; but it is usually a difficult and painstaking task to find these parasites in the tissues of adult cadavers with the late lesions of syphilis.

It is not possible, therefore, to express the true incidence in syphilis. Surveys based upon clinical findings, the Wassermann test and gross pathological changes indicate an incidence varying from about 2 to 20 per cent. with a general average of about 10 per cent. of the population in the United States. This figure is undoubtedly too high for some localities and decidedly too low for others, as the incidence of syphilis varies according to social conditions and practices. On the other hand, I believe that Warthin's incidence of 30 to 40 per cent. is too high for rural communities and the middle class of people generally. At any rate clinical, serological and pathological surveys have proven that syphilis is a wide spread disease involving all peoples, regardless of rank and station and of tremendous economic importance. After all, figures expressing incidence on any basis of computation are of relative value only and of no aid in the diagnosis of any one individual; suffice for us to realize that syphilis concerns practically every speciality in medicine, that our resources for clinical, serological and pathological diagnosis are limited, and that under the best of conditions we are especially likely to fail in the diagnosis of the disease during life and to a lesser extent upon examination of the tissues after death.

Pathology of Syphilis in Relation to Chemotherapy.—In the chemotherapy of syphilis it is required that the patient and not the disease shall be treated and under some conditions this may render inadvisable or impossible any attempts toward bringing about the complete eradication of all spirochetes from the tissues. For the destruction of the spirochetes, however, we must depend upon medicinal compounds of known spirocheticidal prop-

erties. Antibodies produced by the host are not sufficient for bringing about spontaneous cure in more than rare and exceptional instances. Destruction of spirochetes by the products of necrosis of gummas and other syphilitic deposits occurs only in the localized areas directly involved. Successful chemotherapy is the mainstay of treatment and success depends upon the proper administration of a medicinal that is spirocheticidal in non-toxic amounts, that is able to reach the spirochetes and to which the spirochetes are susceptible.

These conditions are optimum in the early stages of the disease—the earlier the better. The chemotherapy of syphilis in the clinical primary and secondary stages offers the best chances for complete eradication of all spirochetes, because the parasites in the blood, lymph and lymph spaces of the tissues and organs are accessible to spirocheticidal medicinals brought to the foci of infection by the blood and lymph. Naked parasites, that is, spirochetes without any surrounding wall of lymphocytes and plasma cells are most susceptible and for this reason proper treatment in the earliest stages of the disease yields best results, but spirochetes surrounded by cellular exudates are still approachable, provided fibrosis and especially fibrosis of the blood-vessels, has not occurred.

When spirochetes are first deposited in the tissues, the problem of successful chemotherapy is not greatly complicated by the question of penetrability of the medicament—that is, whether or not the compound may reach the spirochetes if administered properly in sufficient amounts. During the first few weeks or months thereafter this problem is still relatively unimportant, because we know from experiments with rabbits that spirocheticidal substances may still readily reach and destroy spirochetes surrounded by cellular exudates. But in the late lesions characterized by fibrosis and especially fibrosis of the blood-vessels, the problem of chemotherapy is complicated by the question of whether or not the spirocheticidal medicinal compound is able to penetrate these inflammatory tissues and gain access to the spirochetes. I do not believe that the question is one of blood-vessel supply and that spirochetes may locate in a tissue so poorly supplied with arteries that a medicinal absorbed into the blood is unable to reach the parasites; rather it is a question of the condition of the vessels in the diseased foci.

Fortunately *Spirochæta pallida* tends to locate at the periphery of these fibrous lesions rather than centrally and therefore, may be more readily influenced by treatment; centrally placed parasites however, may be destroyed by a lack of pabulum or by the products of tissues autolysis brought about by occluding vascular changes. For this reason it is probably not necessary for a medicinal compound to penetrate a large gumma to effect a therapeutic influence, even though it were possible to do so. From the standpoint of improvement in the chemotherapy of chronic syphilitic lesions, it seems to me that most is to be expected in the immediate future from research devoted to methods for effecting the removal of syphilitic inflammatory exudates and fibrous tissue or increasing the permeability of spirocheticidal compounds for these tissues in order to facilitate the destruction of the spirochetes and neutralization of their products. In this connection the possibilities of discovering new spirocheticidal compounds possessing greater affinity for the organisms and syphilitic exudates along the lines of vital staining are to be kept in mind as previously discussed in earlier chapters, but permeability of fibrosed blood-vessels by spirocheticidal agents remains the most important problem, in the solving of which the configura-

tion of the molecules of the medicinal rather than their size are the important factors.

Aside from the question of the influence exerted upon the spirocheticidal activity of medicinal compounds by histological changes in foci of syphilitic infection, we have for consideration the effect exerted by wide-spread pathological changes upon the toxicity of chemotherapeutic agents for the tissues of the host. It is one thing to express toxicity of a compound for a healthy animal, but an almost entirely different one for a diseased animal with alterations of metabolism and elimination. In this manner the pathology of syphilis very materially influences the chemotherapy of the disease. We may have efficient spirocheticidal agents in arsphenamin, neoarsphenamin, bismuth and mercury and any or all of these may be capable of reaching the spirochetes in the inflammatory exudates, but an individual may not be able to tolerate them in therapetiucally active amounts, or their administration may intensify degenerative lesions in certain organs and notably the liver and kidneys.

In the great majority of cases of early syphilis the general condition of the patients is such that there are no contraindications to active treatment from the standpoint of previous disease. Even in acute tuberculosis one may usually proceed with active treatment when the victim is doubly unfortunate in contracting syphilis. From the standpoint of treatment with arsphenamin and allied products and mercury, the conditions of the kidneys and liver is, however, of much importance and, when these are damaged by preceding disease, due care must be exercised in the treatment of syphilis. Likewise the treatment of syphilis accompanied or complicated by advanced endocarditis and myocarditis must be modified to meet special conditions.

The pathology of syphilis and the general condition of each patient from the standpoint of existing or previous disease may exert, therefore, considerable influence upon the treatment of the disease which may be briefly summarized as follows:

1. Early syphilitic lesions are those dating from the time of invasion of the tissues with *Spirochæta pallida* to the prefibrosis stage. That is, the parasites may be surrounded with lymphocytes and plasma cells but thickening of the blood-vessels with fibrous tissue and the production of fibrous tissue in the lesions have not occurred. Under these conditions the chemotherapeutic compound and antibodies have direct access to the parasites although hindered according to the amount of cellular exudate. For this reason spirochetes with practically no surrounding exudates are apparently most vulnerable to destruction providing they have not acquired a resistance or fastness to the medicament employed.

2. Late syphilitic lesions are those in which fibrosis has occurred and especially fibrosis of the blood-vessels. These lesions protect the spirochetes and hinder or delay the approach of spirocheticidal compounds and antibodies. It is likewise possible that all inflammatory exudates and especially those showing fibrosis, may absorb, fix or inactivate spirocheticidal substances and thereby deviate them from the parasites.

3. Large syphilitic lesions—the gummas—tend to become autosterilized by means of loss of nutrition and necrosis due to vascular occlusion, the products of autolysis and necrosis being probably destructive for *Spirochæta pallida*.

4. Syphilitic lesions, and particularly chronic lesions, may so impair the physiological functions of organs and interfere with the elimination of arsenic and mercury as to reduce tolerance for these spirocheticidal compounds. In other words the pathological changes produced by *Spirochæta pallida*

may alter the pharmacological and toxicological effects of chemotherapeutic compounds and thereby profoundly influence the treatment of syphilis in its later stages.

5. Pathological states due to other diseases preceding or coexisting with syphilis may have a similar influence upon the pharmacological and toxicological effects of antisyphilitic drugs and thereby modify the treatment of syphilis in any of its clinical or pathological stages.

Of course, it is readily understood that in the treatment of syphilis one cannot hope to restore the cells by chemotherapeutic procedures which have been completely destroyed by *Spirochæta pallida* or its products. All we can hope to do is to destroy the parasites, prevent the destruction of more cells and to some extent promote the absorption of the inflammatory exudates. Restoration of function is governed by Nature's capacity for reproduction of tissue and this is controlled in syphilis by the same laws as are operative in other types of tissue injury. Aneurysms may not disappear, nor an aortic regurgitation or the mental stigmata of paresis, although these results are commonly expected by the laity and hoped for by not a few physicians.

Finally, the possibility of chemotherapeutic remedies as arsphenamin and allied agents, mercury and bismuth, producing injuries of capillaries and thereby favoring lodgment of spirochetes in the tissues must be mentioned in the relation of chemotherapy to the pathology of syphilis. There is no evidence to show that such actually occurs, but one should not overlook the possibility of antisyphilitic drugs given in too large doses or over too large periods of time producing degenerative lesions in the liver, kidneys, heart and brain and possibly producing thereby areas of lessened local resistance favorable to syphilitic infection.

Pathology of Syphilis in Relation to Curability and Prognosis.—In Chapter LXXIX, the questions of the curability of syphilis and the criteria of cure are discussed with more detail owing to the practical importance of these subjects, than which none are more important for the victims of the disease and concerning which they seldom fail to ask of their physician an expression of opinion.

Does *Spirochæta pallida* engender such pathological changes that the disease is uncurable in the present state of our knowledge concerning treatment?

It is still too early to express a final opinion of the end results of treatment with arsphenamin and neoarsphenamin, but by all the most rigid criteria of cure applicable during life I believe that complete cures were obtained in many instances with the older forms of treatment with mercury and iodids and that the percentage of cures is probably higher at the present time with the methods of modern chemotherapy. I am absolutely sure of our ability to cure the disease in the lower animals even when treatment is delayed until chronic lesions have developed although we cannot produce in rabbits and monkeys chronic vascular and neural lesions of the degree encountered in human subjects with the late lesions of syphilis. The increasing frequency with which individuals are reported having contracted genuine new infections after the treatment of a preceding attack of the disease lends great weight to the opinion that, when syphilis is properly treated in the primary and secondary stages at least, complete cures are obtainable.

It cannot be denied that, since the advent of arsphenamin and allied products in the treatment of syphilis, many physicians and the laity alike are deluded into false impressions of complete cure by the dissipation of the external lesions of the disease by a few injections of the medicament only to

have lesions develop at a later time; furthermore, opinions are at wide variance on the questions of the kind and amount of treatment to employ, but in general terms thorough treatment over one to two years of time apparently effects complete cures in cases of early syphilis.

Warthin states that he has found histological evidences of syphilis and indeed, the spirochetes themselves, in the tissues of numerous subjects after death who in life had been treated for syphilis and were retarded as "cured." But it is well known that the treatment of syphilis is subject to wide variations in practice since it may vary all the way from a few months of treatment with pills of protiodide of mercury with potassium iodid by mouth, or treatment with iodids alone or with sodium cacodylate alone, all of which are devoid of spirocheticidal properties in the amounts commonly employed, to thorough and prolonged treatment with arsphenamin or neoarsphenamin, mercury and the iodids. Naturally Warthin became very skeptical about the question of the cure of syphilis under the conditions of his work, but in my opinion his pessimism is not warranted or generally applicable to the curability of syphilis especially in its early stages when the disease is thoroughly treated by modern methods.

The older methods of treatment with mercury and iodids, prior to the introduction of arsphenamin and its allied products, probably did fail to completely cure many cases of syphilis; the incidence of late lesions seen to-day is ample proof of this assertion. Furthermore, we know that it is difficult to cure syphilis of the lower animals and especially of the rabbit, with these older methods of treatment.

It is to be admitted likewise that syphilis is not as quickly and easily cured in the sense of complete eradication of all spirochetes from the tissues as believed when salvarsan was first introduced in the treatment of the disease. Furthermore, it is still too early to judge what may be the late or final results in cases treated with salvarsan and its allied products. Thorough histological studies are required of the tissues of subjects treated during life with these compounds, for evidences of syphilitic infection before final opinions may be expressed. But it is certain that we are much better able to cure syphilis of the lower animals with these products and have the results checked up by rigid inoculation and histological examinations and I believe that the majority of physicians especially skilled and experienced in the present day methods of treating the disease are convinced that complete cures are obtainable when adequate treatment is instituted during the early stages at least.

The complete cure of syphilis is certainly more doubtful when treatment is instituted in the late than in the early stages of the disease. Treatment must be more prolonged, although it may be milder in order to avoid tissue injury by the spirocheticidal agents. It may not be possible to sterilize the old fibrotic lesions although the fresher lesions developing in the clinically latent and tertiary stages due to continued dissemination of spirochetes into other tissues and organs, are just as susceptible to sterilization by adequate treatment as similar lesions in the early clinical stages of the disease. Furthermore, even though complete sterilization is effected in the older lesions by persistent and prolonged treatment, the results of the tissue injury may never disappear. In other words spirocheticidal compounds do not bring about the resolution and absorption of inflammatory exudates and fibrous tissue although the iodids may aid in this process; neither do they restore the cells destroyed by the infection although the removal of the spirochetes and their toxic products may permit damaged cells to recover with restoration of their functions. Spirocheticidal compounds bring about the death of the

parasites and prevent further extension of the existing lesions and the development of new ones; absorption and repair then progress along the same lines as in other forms of tissue injury due to infection.

I believe, therefore, that the complete cure of syphilis is obtainable in the majority of cases adequately treated in the early stages of the disease. In cases presenting the late lesions adequate treatment may produce "clinical cures" in a goodly proportion of individuals, in the sense that old existing lesions are held in check, new lesions cured and further extension of the disease into new tissues and organs prevented. The problem of effecting complete cures in the early stages is not usually embarrassed by general pathological changes reducing resistance and complicating therapy. In the late stages the difficulties of effecting "clinical cure" or complete cure in the sense of complete eradication of the parasites are in more or less direct proportion to the age of the lesions, their size and location and the general condition of the patient with particular reference to the state of the liver and kidneys and allergy or tolerance to arsenical and mercurial compounds as influencing the amount of treatment that may be safely administered.

CHAPTER XXXIX

WASSERMANN AND PRECIPITATION TESTS IN RELATION TO THE DIAGNOSIS AND PROGNOSIS OF SYPHILIS, WITH SPECIAL REFERENCE TO THE KOLMER COMPLEMENT-FIXATION REACTION

Since the discovery of the complement-fixation reaction in syphilis by Wassermann, Neisser and Bruch and independently by Detre, in 1906, the test has undergone many changes, both in the theory of its mechanism and in its technical details. Despite, however, much use and abuse, it has splendidly withstood the vicissitudes of time and fortune, and, owing to an increase of our knowledge of its mechanism and technic, is proving to-day of increasing value, not only in the diagnosis of syphilis but as a guide to the treatment of the disease as well. An enormous literature has accumulated upon this subject, but much of it is worthless owing to obvious errors in technic; one result, however, has been to create a great deal of confusion, distrust and skepticism in the minds of many physicians regarding the practical value of the test. Altogether too frequently short-cut methods and various modifications masquerading under the common designation of "Wassermann test," has been used by technicians lacking in experience and skill or driven to return results in the shortest possible time, with the result that numerous errors may be committed in the way of both falsely positive and falsely negative reactions, unless due care and skill are applied in the conduct of the test.

As I hope to point out in this chapter, conflicts between the clinical and serological diagnosis of syphilis are almost unavoidable, in some cases at

least; but I believe it is the concensus of opinion among physicians of wide experience in syphilis that, when the complement-fixation test is properly conducted, the reactions are of great value not only in the diagnosis of syphilis and especially chronic syphilis in its latent stages, but as a guide and control to treatment.

Since this treatise is devoted to the treatment of syphilis rather than diagnosis, it is not required to consider in detail the serum diagnosis of the disease but a few brief remarks may not be amiss because of the great practical importance of the subject and especially Wassermann-fastness in relation to treatment.

Specificity of the Complement-fixation Reaction in Syphilis.—The complement-fixation reaction in syphilis is not a biologically specific reaction, since the "reagin" or so-called "Wassermann substance" occurring in the serum and spinal fluid of syphilitic subjects is capable of flocculating the lipoids of any normal tissue. If the reaction occurred only with lipoids of extracts of syphilitic tissues, it would be a biologically specific reaction, but this certainly is not the case. Practically, however, the complement-fixation reaction is specific for syphilis in those places where frambesia or yaws and trypanosomiasis are rare or of unknown occurrence. In other words, the "reagin" is produced only in syphilis and frambesia and possibly in trypanosomiasis, although, as previously stated, the literature on the Wassermann reaction and especially the early literature, shows that some one at some time claims to have observed positive reactions in almost all the non-syphilitic diseases of human beings.

This subject of specificity is probably the most important question of all in relation to the complement-fixation reaction in syphilis. It is imperative that serologists adopt a method which experience has taught them to regard with confidence, and especially the weakly positive reactions. There is no special merit in observing positive reactions with the sera of frankly syphilitic individuals; indeed, no more than confirming the diagnosis of fracture of a long bone by *x*-ray examination when the deformity is obvious. The complement-fixation test must detect the clinically latent and doubtful cases, and, since the sera of these may yield only weakly positive reactions, the technic should be such that these reactions may be accepted with confidence.

I believe that it is technically possible to render the complement-fixation test practically specific for syphilis in this country, since frambesia or yaws is of rare occurrence. To this end, experience and careful work on the part of the serologist are of prime importance; the best of methods cannot yield uniformly satisfactory results in the hands of inexperienced and careless workers. Altogether too much mischief has been done by short cut methods and by insufficiently trained technicians, and the physician should exercise due care in the selection of a serologist, especially if the results of complement-fixation tests are to be accepted as guiding rather than merely confirming a clinical opinion or diagnosis.

From the standpoint of technic I hope that my new method[1] will be given a fair trial. It is significant that in over 68,000 tests, including my own, in addition to those reported by Schamberg and Klauder,[2] Shivers,[3] Harper and Curtis,[4] Palmer and Gibbs,[5] Kilduffe,[6] Schamberg and Greenbaum,[7] and others, the literature having been recently reviewed by Kilduffe,[8] falsely positive reactions have been conspicuously mentioned as not having been observed.

Finally, it should never be overlooked that syphilis confers no immunity to other diseases and that the active or latent case of syphilis may present a lesion that is not syphilitic as, for example, a tuberculous ulcer in the larynx,

a cancer, etc. Not infrequently a positive complement-fixation reaction with the serum of a latent case of syphilis presenting a tuberculous ulcer is regarded as evidence of a non-specific reaction. Lesions that do not show evidences of healing after antisyphilitic treatment should always be suspected as being non-syphilitic, even though the patient has syphilis and yields a positive Wassermann reaction.

Sensitiveness of the Author's New Complement-fixation Reaction in Syphilis.—Next to specificity, the sensitiveness of the complement-fixation reaction in syphilis is a quality of primary importance. In their anxiety to avoid non-specific or falsely positive reactions, many serologists employ methods of reduced sensitiveness, being willing to "miss" many cases of syphilis in order that the positive reactions may be acceptable. I believe that this is correct in principle, but at the same time serologists should strive for a method that is as sensitive as consistent with specificity. As previously stated, the merit of the complement-fixation test is not merely in confirming a clinical diagnosis that may be obvious and sure enough, but in aiding in the diagnosis of the clinically difficult and doubtful cases and, indeed, of cases in whom the diagnosis by historical and clinical data is not possible.

I believe it is to be admitted that the history is frequently misleading; that some individuals purposely and persistently deny all knowledge of venereal infection, while a still larger group are perfectly sincere and truthful in denying all knowledge of the disease. The latter is readily understood when it is remembered that the primary lesion may be small and regarded clinically as herpes, chancroid or some other non-syphilitic erosion, and that in women the primary lesion may not be detected at all. Furthermore, extragenital lesions may not be suspected, as also latent congenital infections. I believe it is to be likewise admitted that the disease in its chronic latent stages may escape clinical detection by even the most experienced physicians and that chronic active lesions may be so small, atypical or so situated as frequently to escape detection. It has been said that the diagnosis of syphilis cannot be made by serological examinations; rather, I believe, that not infrequently the diagnosis is not possible by any other means.

Not every case of chronic latent syphilis requires treatment; there may be well-defined contra-indications and it may be wisely decided to leave well enough alone, but there can hardly be a difference of opinion on the advisability of having a method for the specific detection of as many cases of syphilis as possible, even though treatment is not given and the results are not imparted to the patient.

At best I am convinced that no serological test can ever be expected to detect all cases of syphilis. The "reagin" or "Wassermann substance" appears to be a product of the lymphocytes and other cells in the foci of infection, and, since Warthin has shown that *Sp. pallida* may be so dormant as to live in the heart muscle and elsewhere without the usual admiring circle of lymphocytes, it is hardly to be expected that sufficient amounts of "reagin" will be present in the blood. The Wassermann reaction is an index of infection and its strength bears some relation to the activity of the spirochetes. This, however, may not be appreciated clinically, because active lesions in physiologically unimportant tissues may yield few symptoms, whereas a small lesion or series of small lesions in important tissues, as in the posterior columns of the spinal cord, may produce marked symptoms with relatively small amounts of "reagin" in the blood and consequently with the production of negative or weakly positive reactions.

Interpretation and Method of Recording the Kolmer Complement-fixation Reaction in Syphilis.—A uniform method for reporting and recording

complement-fixation reactions in syphilis would greatly aid in avoiding confusion and misunderstandings in this subject; Kilduffe and others have published pleas for the adoption of a standard method.

Possibly the adoption of the usual terminology as *strongly positive, moderately positive, weakly positive* and *negative* or some modification of these terms, would aid somewhat but means very little as long as many different complement-fixation methods are in use, because what may be a strongly positive reaction with one method may be a weakly positive with another. Indeed, this is actually the case with my new method which, on account of its increased sensitiveness, commonly yields strongly positive reactions with sera yielding weakly positive reactions with my former three antigen method.

There is but little hope of ever being able to devise a terminology for expressing complement-fixation reactions in conformity with the clinical aspects or activity of syphilis, because the reactions may vary from strongly positive in cases of latent syphilis with no demonstrable lesions, to weakly positive and, indeed, negative, in exceptional cases of acute virulent syphilis.

As previously stated, the question of primary importance is whether the serum or spinal fluid of any given case does or does not give a positive reaction regardless of the strength of the reaction or the amount of serum or spinal fluid employed. This serves for both diagnosis and as a serological guide to the treatment of syphilis, and is sufficient if true positive reactions, including those that are but weakly positive, are acceptable as evidence of syphilis and in general terms as an indication for treatment.

But, if the degree of complement fixation is acceptable as an index of the degree of spirochetic activity even though the latter is not always to be evaluated clinically, something more is to be gained by measuring the strength of the reaction. Furthermore, when the fixation test is being employed as a guide to treatment, a measure of its strength is of some value, even though this may fluctuate and does not usually proceed from the positive to the negative state in a uniform manner except in cases of acute syphilis treated with arsphenamin or allied products.

In my new quantitative method each serum is tested in graded amounts after the method of Detweiler,[9] the amounts being 0.1, 0.05, 0.025, 0.005 and 0.0025 c.c. Spinal fluids are likewise employed in graded amounts as 0.5, 0.25 c.c., etc. The test requires six test tubes instead of two and the time required is slightly greater, but a method has been worked out[10] whereby these dilutions are quickly set up, and after some practice has been gained, as many as 20 to 40 sera or spinal fluids can be diluted within an hour.

This method not only yields a truer quantitative reaction than the older two-tube test, but likewise increases the accuracy of the reactions. Contrary to usual impressions, the largest dose of serum does not always yield the most sensitive reaction. One naturally supposes that to increase the delicacy or sensitiveness all that is necessary is simply to increase the amount of serum employed; but this is far from being true. In the first place the larger amounts may yield anticomplementary reactions, but even if this does not occur, something in the serum tends to interfere with complement fixation so that a large dose of serum as 0.2 c.c. may actually yield a weaker reaction than 0.05 c.c. Most serologists believe this is due to natural antisheep hemolysin, but in my opinion this factor does not explain all such reactions. Apparently some other serum constitutents, as the proteins or salts, may interfere with the fixation of complement. However, while the mechanism is in doubt the observed facts are not and in my new method, at least, 0.1 c.c. of syphilitic serum may actually yield a weaker reaction than 0.05 c.c. For this reason alone I believe it is necessary in the interests of the best work

to test every serum in at least two amounts and the added labor of using the full series of five dilutions is so slight that the complete quantitative test is very much to be preferred for routine work. I do not know definitely if the same is true of other methods, but I surmise that in all tests employing single doses of serum as 0.1 or 0.2 c.c., the same error is possible, although I have observed no evidence of this error in tests employing spinal fluids.

In my new method, therefore, each serum and spinal fluid is tested in five graded amounts, the sixth tube being the serum control. *The results are expressed according to the smallest amount of serum or spinal fluid yielding a positive reaction;* at the same time the degree of fixation after the ++++, +++, ++ and + method may be expressed for each tube showing fixation. In other words, the test yields a two-way quantitative reaction: (*a*) according to the smallest dose of serum or spinal fluid yielding a positive reaction of any degree and (*b*) according to the degree of fixation in the individual tubes. The former is the more important and more definite in results; the latter is variable because so much depends upon the human eye and what one person may read as a +++ another may read as ++. I have described a reading scale, however, which reduces this error.

According to my method the reactions are reported as follows:

Very strongly positive, if complement fixation of any degree occurs in the first four or five tubes.

Strongly positive, if fixation of any degree occurs in the first three tubes.

Moderately positive, if fixation of any degree occurs in the first two tubes.

Weakly positive, if fixation of any degree occurs in the first tube.

Negative, if hemolysis is complete in all.

At the same time, the readings on each tube showing fixation are recorded after the ++++, +++, etc. method of Citron. A few examples will suffice for purposes of illustration:

0.1 c.c. ++++
0.05 c.c. ++++
0.025 c.c. ++
0.005 c.c. +
0.0025 c.c. −

This reaction was reported as *very strongly positive* (4421−).

0.1 c.c. ++++
0.05 c.c. ++++
0.025 c.c. +++
0.005 c.c. −
0.0025 c.c. −

This reaction was reported as *strongly positive* (443−−).

0.1 c.c. ++
0.05 c.c. +++
0.025 c.c. −
0.005 c.c. −
0.0025 c.c. −

This reaction was reported as *moderately positive* (23−−−) and is an example of when the 0.05 c.c. amount of serum yielded a stronger reaction than the 0.1 c.c. dose. This, however, does not influence the general report of moderately positive.

Occasionally the reaction is about as follows:

0.1 c.c. −
0.05 c.c. ++
0.025 c.c. −
0.005 c.c. −
0.0025 c.c. −

This reaction was reported as *moderately positive* (−2−−−) even though the largest dose of serum (0.1 c.c.) reacted negatively. This occurs about once in every 200 to 300 sera and is an example of the importance of using a quantitative method.

0.1 c.c. +++
0.05 c.c. −
0.025 c.c. −
0.005 c.c. −
0.0025 c.c. −

This reaction was reported as *weakly positive* (3— — — —).

0.1 c.c. —
0.05 c.c. —
0.025 c.c. —
0.005 c.c. —
0.0025 c.c. —

This reaction was reported as *negative* (— — — — —).

Prognostic Value of the Complement-fixation Reaction in Syphilis, and the Significance of the "Wassermann-fast" Reaction.—The most difficult problem in the treatment of syphilis is the proper interpretation and management of those cases where sera yield persistently positive complement-fixation reactions in spite of active and prolonged treatment. Not infrequently many such individuals appear clinically free of syphilitic lesions and in good general health, although thorough examinations are apt to disclose evidences of syphilitic infection in the cardiovascular, central nervous or other organs. Opinions are divided, however, among syphilographers of wide experience regarding the significance of such reactions and the best means of treatment.

The *frequency* of "Wassermann-fast" cases of syphilis is difficult to compute, but the condition is relatively common and occurs probably in from 10 to 20 per cent. of cases of syphilis in clinic and private practice of to-day. Of cases of primary and secondary syphilis treated intensively and adequately with arsphenamin or neoarsphenamin, the condition is not likely to develop in more than 5 per cent., but of cases of latent and chronic syphilis, including congenital cases who have had inadequate treatment or none at all in the earlier stages, it is found that least 20 to 30 per cent. will continue to give presistently positive complement-fixation reactions after thorough courses of treatment with arsphenamin or neoarsphenamin and mercury. For example, of 458 syphilitic patients who had received twelve to twenty-nine arsphenamin injections combined with mercurial inunctions, the average being fourteen injections and ninety inunctions in eleven months, Stokes and Burman[11] found 6.6 per cent. of primary and secondary cases and 22 per cent. of latent, late and hereditary cases remained persistently Wassermann-positive.

Just when a case should be regarded as "Wassermann-fast" is a matter of individual judgment and particularly so, in view of the fact that persistent treatment of some cases ultimately results in eradicating this quality of the serum. Any case of primary and secondary syphilis yielding persistently positive reactions after the first six months of treatment described in Chapter LXXI is regarded by me as possibly "Wassermann-fast" and cases of chronic syphilis (latent and active) yielding persistently positive reactions after one year of mixed treatment can be regarded as "Wassermann-fast." These statements refer only to tests with blood serum; even after negative reactions occur with blood serum, the cerebrospinal fluid may continue to yield positive reactions as well as pleocytosis, increase of proteins and positive colloidal gold reactions. Undoubtedly the percentage of "serological fast" cases of syphilis, that is, cases showing abnormal changes in the spinal fluid as well as positive blood serum reactions, would be increased if statistics were based upon spinal fluid examinations as well as blood examinations.

The *cause* of the "Wassermann-fast" condition is naturally of prime importance in relation to both prognosis and treatment. Can the condition be possibly due to the effects of arsphenamin, neoarsphenamin and allied compounds or mercury, upon the liver or other internal organs, with the production of such substances of cellular degeneration as may result in physico-chemical changes in the serum of a character to yield positive complement-fixation reactions? As stated in Chapter XLVI, we know that these drugs are capable of producing pathological changes in the liver, kidneys, etc.,

and the subject is not to be passed over too lightly. Strickler, Munson and Sidlick[12] have asserted that the administration of arsphenamin and neoarsphenamin to supposedly non-syphilitic human subjects resulted in the production of temporarily positive Wassermann reactions while mercury was without such effects;[13] but in my experiments[14] with rabbits treated with arsphenamin, neoarsphenamin and mercury, no evidence of such reactions was found and these results have been recently confirmed by Kilduffe.[15]

It cannot be overlooked, however, that the complement-fixation reaction is frequently more strongly positive during and immediately after a course of treatment than after a period of rest. It is commonly advised to wait for two or three weeks after a course of treatment before conducting the complement-fixation test, in order to avoid securing a falsely negative reaction which is believed possible immediately after treatment. On the contrary, I have usually found the reverse; that is, the complement-fixation test frequently yields a positive reaction immediately after a course of treatment, which gradually becomes weaker and sometimes negative during a period of two to four months without specific medication. This suggests that the drugs may be responsible for the positive reacting quality of the serum through their effects upon the liver or other internal organs, but I do not believe such is the case. In my opinion these effects are due to the production of "reagin" by spirochetes actively stimulated by the drugs and that as treatment subsides the surviving spirochetes become latent or less active with a reduction in "reagin"-production.

No evidence has yet been produced to disprove the commonly accepted theory that persistently positive Wassermann reactions are due to anything other than the presence of active spirochetes in the tissues.

Just why spirochetes in these chronic latent and active lesions are so resistant to destruction cannot be stated in exact terms. The condition is frequently passed over with the statement that they are protected by fibrous tissue which, being largely free of blood-vessels, reduces the chances of medicinal compounds reaching the parasites. I believe that such may be the case, in part at least, coupled with the fact that the syphilitic mesarteritis may bring about a high degree of vascular occlusion and reduce at least the rate of penetration of spirocheticidal agents in the inflammatory tissue of infection. For this reason I believe the guiding principles of treatment in such cases should be the administration of small doses over long periods of time, along with the administration of the iodids for the possible aid they may render in aiding access of spirocheticidal compounds by the softening and removal of fibrous tissue and lymphocytic exudates.

In a thorough study of 101 cases by Stokes and Busman previously referred to, the value of thorough clinical and roentgenological examinations is emphasized and shows how frequently lesions may be detected when superficial examinations may yield to false impressions. It is commonly stated that most "Wassermann-fast" cases show syphilitic involvement of the central nervous system, but in the series studied by Stokes and Busman, cardiovascular changes were found in 44 per cent., neural involvement in 30 per cent., hepatic, splenic, and gastric lesions in 21 per cent., and other types in from 10 to 17 per cent. In this series only 10 patients presented no other evidences of syphilis than their positive complement-fixation reactions. In other words the condition of "Wassermann-fastness" of the serum is not necessarily a sign of neurosyphilis and lends no support to the theory of the existence of neurotropic strains of *Sp. pallida*. Indeed, as discussed in Chapter LXXVI, cases of neurosyphilis with "Wassermann-fast" blood reactions quite commonly show lesions in the cardiovascular and other organs

as well, as recently shown in a study by Moore and Kemp.[16] Certainly "Wassermann-fastness" is not to be regarded as a trivial condition and such cases should at least receive periodic examinations and courses of treatment for the balance of life. I am in the habit of explaining the condition and giving comfort to patients by drawing an analogy to dental caries, in that a complete "fixing up" of the teeth this year does not guarantee against the development of cavities in the future and that the best means of avoiding pain and distress is having periodic examinations of the teeth once or twice a year.

Diagnostic Value of the Precipitation Reactions in Syphilis.—I believe the mechanism of the Wassermann reaction is due to the adsorption or fixation of complement by aggregates or precipitates of lipoids of the tissue extract employed as antigen, as the result of a physico-chemical reaction brought about by the syphilitic "reagin" in the blood serum or spinal fluid. This idea is an old one and it is not surprising that numerous attempts have been made, since the original efforts of Michaelis[17] in 1907, to so alter the proportions of antigen and serum employed as to render visible to the naked eye these flocculent masses, in order to thereby simplify the serological diagnosis of syphilis. The reactions of Porges and Meier,[18] Herman and Perutz,[19] Meinicke,[20] Vernes,[21] Sachs and Georgi,[22] Dreyer and Ward,[23] Kahn,[24] etc., are reactions of this kind and the Sachs-Georgi and Kahn tests have especially attracted considerable attention.

My opinion of them in the diagnosis of syphilis is set forth in detail elsewhere[25] and is largely based upon observation of the results secured by Strumia[26] in my laboratory in a study of the Meinicke, Sachs-Georgi, Kahn and Vernes methods. I believe that these flocculation tests and particularly the Kahn test, are of distinct value as serological controls for the complement-fixation reaction in the diagnosis of syphilis, but the preparation of the antigen upon which their success so largely depends is just as intricate and important as in the complement-fixation reaction. It is true that the technic of setting up the tests is simpler than the latter, but it is likewise true that it is much more difficult to interpret and evaluate the doubtful and weakly positive reactions. With the sera of frankly syphilitic and non-syphilitic individuals, the precipitation reactions run closely parallel with the complement-fixation reactions, but, with the clinically latent and doubtful cases of syphilis in which group serological tests should be of most aid in diagnosis, the complement-fixation reaction has generally proven the superior method. Furthermore, the precipitation tests are not as successfully conducted with cerebrospinal fluids as is the complement-fixation reaction. I believe that these flocculation tests are of value, but that they require almost as much care in the preparation of the reagents as the complement-fixation test, and while it is true that they require less time, this constitutes no advantage in my opinion as long as the question of accuracy in results is involved. They cannot be made to yield quantitative reactions in the same manner as the complement-fixation test employing varying amounts of serum and are, therefore, much less useful for serological guidance in treatment. I now employ the Kahn test routinely as a control on the complement-fixation test; every once in a while the complement-fixation test yields a true positive reaction when the precipitation reaction is negative, but the reverse occurs just as frequently and both should be employed for obtaining the best results. In my experience the precipitation test is also more likely to yield persistently positive reactions during treatment, but whether these should be taken as indicating further treatment when the complement-fixation reactions are repeatedly negative, cannot be stated at the present time.

CHAPTER XL

WASSERMANN TEST IN RELATION TO THE TREATMENT OF SYPHILIS AND AS AN INDEX OF CURE, WITH SPECIAL REFERENCE TO THE KOLMER COMPLEMENT-FIXATION REACTION

Within a few years after the discovery of the Wassermann reaction, Citron,[1] Bruck and Stern,[2] Hochne,[3] Pedersen[4] and others published observations showing that under the influence of mercurial treatment the sera of syphilitic individuals tended to yield weaker Wassermann reactions and in some instances resulted in negative reactions. With the advent of salvarsan in the treatment of the disease in 1910, interest in this subject was greatly renewed, and Nichols,[5] Nichols and Fordyce,[6] Fox,[7] Citron,[8] Weschselmann,[9] McIntosh,[10] Michaelis,[11] Muller,[12] Noguchi and Bronfenbrenner,[13] Craig[14] and others were among the first investigators calling attention to the fact that treatment with this substance sometimes resulted in producing negative mcoplement-fixation reactions along with symptomatic improvement. Of course it is not surprising that the earlier reports varied greatly in the degree of influence of treatment upon the Wassermann reaction, but they served to establish the important principle that the complement-fixation reaction in syphilis is influenced by mercury and salvarsan and constitutes a very valuable guide in treatment and a criterion of cure.

Mechanism of the Influence of Chemotherapy upon Complement Fixation in Syphilis.—While the exact nature of the substance in serum and spinal fluid responsible for complement fixation in syphilis is unknown, it is, how-

ever, directly or indirectly a product of *Spirochæta pallida* and, as stated in the preceding chapter, bears a more or less direct relation to the degree of spirochetic activity.

The administration of spirocheticidal compounds, as arsphenamin and allied products, bismuth, mercury, etc., results in a diminution of the complement-fixing substance, by reducing the numbers and activity of the spirochetes; on the other hand, however, the administration of these compounds in subcurative doses may result in a temporary increase of complement fixation by increasing the numbers and activities of *Spirochæta pallida* in the tissues. The latter is well known as the provocative Wassermann reaction and is considered in more detail in Chapter XLI.

There are no reasons for supposing that arsphenamin and allied products, bismuth and mercury are capable of themselves of producing substances in the serum yielding positive complement-fixation reactions. Arsphenamin in blood drawn immediately after the intravenous injection of this substance has no such influence, although it is possible that compounds administered in too large doses may bring about degenerative changes in the liver, kidneys, etc., and an increased anticomplementary activity on the part of the serum.

It is to be expected, therefore, that any therapeutic measure resulting in a decrease of spirochetic activity would be followed in time by a decrease in the degree of complement fixation. However, in chronic active or latent syphilis, the decrease is not regular or progressive, but is apt to be up and down; this is readily understood when it is remembered that during treatment the numbers and activity of spirochetes probably fluctuate but with a gradual tendency toward a decrease.

Specific medication in syphilis may, therefore, either temporarily increase the strength of the Wassermann reaction by temporary increase of spirochetic activity or gradually bring about a decrease by destruction of the parasites. These serological changes, however, may not bear a relationship to the clinical progress of syphilis, and for this reason some syphilologists do not accept the complement-fixation reaction as of value in guiding the treatment of the disease. I will, however, later discuss this phase of the subject.

Stage of Syphilis in Relation to the Influence of Treatment upon the Complement-fixation Reaction.—As would be expected, the earlier treatment of syphilis is instituted the better are the clinical results and the same is true in relation to the influence of treatment upon the complement-fixation reaction. Craig[15] has published statistics based upon his test in the army, showing that in primary and secondary syphilis salvarsan treatment is much more efficacious in bringing about negative reactions than in latent and tertiary syphilis and in the former somewhat better than in the latter.

As I shall shortly discuss in relation to the influence of arsphenamin and neoarsphenamin treatment upon reactions with my new test, the power of the serum for fixing complement usually decreases progressively and in an orderly manner to the negative reaction in primary and secondary syphilis, whereas in latent and tertiary syphilis the effects are more irregular and apt to be in the nature of unexpected increases and decreases with but a tendency to become progressively weaker even in those cases which may be suspected as being "Wassermann-fast."

These effects are readily understood. In primary syphilis the spirochetes have not been widely disseminated and are more readily reached and destroyed by arsphenamin and neoarsphenamin; consequently the complement-fixation reactions tend to become progressively weaker and are more profoundly influenced. Indeed, best results in the treatment of syphilis are

observed in those cases in which treatment is begun before positive serum reactions are obtained and in which, by means of adequate treatment, they never become positive. In chronic syphilis, on the other hand, spirochetes are not as readily and quickly destroyed; treatment may stimulate them in some instances followed by stronger complement-fixation reactions, or destroy large numbers at another time followed by a reduction in complement-fixing power. Apparently the degree of influence of treatment upon the complement-fixation reaction is a rough index of the degree of curative influence, although in chronic syphilis it may be possible that cells stimulated to produce the "reagin" may continue to do so for a period after all spirochetes have been actually destroyed in a focus of infection.

Degree of the Complement-fixation Reaction in Relation to Its Disappearance under Treatment.—In a general way, cases of syphilis in any given stage of the disease presenting strongly positive complement-fixation reactions before treatment is begun require more treatment for dissipating the reaction than cases beginning with weakly positive reactions. This is especially true in primary syphilis, but in chronic syphilis exceptions occur so frequently that the relation is by no means a constant one. Not infrequently cases presenting weakly positive reactions at the outset are followed by strongly positive reactions after a few doses of neoarsphenamin or arsphenamin and require more treatment for negative reactions than cases presenting active lesions and strongly positive reactions at the beginning of treatment. In acute syphilis, in either the primary or secondary stages, the physician may confidently expect negative reactions with adequate treatment more quickly if the reactions are weakly or moderately positive than if the reactions are very strongly positive; in chronic syphilis, however, and especially in the latent stages when the reactions are apt to be weakly positive, great caution is required in prognosis and it is always to be expected that, contrary to expectations, the reactions after the first few doses of arsphenamin and neoarsphenamin may be actually stronger than at the beginning followed by a progressive weakening. This is apparently due to a provocative influence of treatment and should profoundly influence the kind of treatment employed; for example, to give such a patient one or two injections of neoarsphenamin may actually do more harm than good, if one is to judge according to the influence exerted upon the complement-fixation reactions.

Technic of the Complement-fixation Test in Relation to the Influence of Treatment and Cure of Syphilis.—It is scarcely necessary to state that the technic of the complement-fixation test bears a very important relation to this subject of the influence of treatment upon serological reactions. When a sensitive method is used, it is readily understood that the reactions remain positive for a longer period of time than when less sensitive methods are employed.

For example, tests conducted after the original Wassermann technic, except that an alcoholic extract of syphilitic liver is employed as antigen instead of a saline or water extract, yield negative reactions under treatment much sooner than tests employing cholesterolized extracts. In other words, the technic employed with special reference to the antigen exerts a tremendous influence upon the reactions and it is a serious error to rely upon the complement-fixation test as a guide in therapy unless the test is known to yield as sensitive reactions as possible with specificity. From 1907 to 1910 reports on the influence of treatment upon the Wassermann reaction were based upon the use of mercury and the iodids, and the tests were usually conducted according to the original Wassermann method; the latter, in a way, was fortunate because, if the earlier investigators had employed the more

sensitive antigens and methods available to-day, they probably would not have noted sufficient influence of mercury upon the reactions to consider worth while recording their observations in literature. A few examples may better explain this very important relation of technic to the value of the complement-fixation reaction as a guide in treatment and a criterion of cure. In my former method, three antigens were employed, namely, a cholesterolized alcoholic extract of beef heart, a plain alcoholic extract of syphilitic liver and an extract of acetone insoluble lipoids of beef heart. The technic was otherwise essentially the same as the original Wassermann test except that one half amounts of each constituent were employed. The new method, however, employs a new antigen of superior sensitiveness, a primary incubation of 18 hours at 6° to 8°C., followed by ten minutes in a water-bath and numerous other technical improvements. In a series of cases in my practice treated exclusively with neoarsphenamin in dose of 0.9 gm. twice weekly, the amount of treatment required for two to five consecutively negative complement-fixation reactions were as shown in Table 5:

TABLE 5.—NUMBER OF INJECTIONS OF NEOARSPHENAMIN REQUIRED TO PRODUCE NEGATIVE REACTIONS WITH THE OLD AND NEW COMPLEMENT-FIXATION TESTS

DIAGNOSIS	OLD TEST			NEW TEST
	CHOLEST. ANTIGEN	ALC. SYPH. LIVER ANTIGEN	ACET. INSOL. LIPOID ANTIGEN	
Primary syphilis	8	3	6	11
Secondary syphilis	10	5	7	14
Secondary syphilis	13	6	9	18
Secondary syphilis	10	4	8	12
Chronic (latent) syphilis	18	11	15	32
Chronic (active) syphilis	23	14	18	41
Chronic (active) syphilis	17	11	12	26

As shown in this table Wassermann tests conducted with a plain alcoholic extract of syphilitic liver yielded negative reactions under treatment much sooner than reactions conducted with Noguchi's antigen of acetone insoluble lipoids and very much sooner than reactions conducted with a cholesterolized extract of beef heart. For any physician who desires to secure negative Wassermann reactions most speedily under treatment, I recommend the original Wassermann test conducted with an antigen of alcoholic extract of syphilitic liver, beef heart or guinea-pig heart with a warm primary incubation of one hour in a water-bath or incubator. But if he stops treatment on the basis of a negative reaction obtained with such a technic or even upon a series of such negative reactions, I am absolutely sure that the majority of his patients will subsequently develop positive reactions and otherwise show the results of insufficient treatment. If such a test is employed the antigen should be an acceptable cholesterolized extract, because this antigen yields much more sensitive reactions that are specific under proper technical conditions and guarantees a more thorough treatment than would otherwise be the case.

Positive reactions with my new method usually require still more treatment for reduction to negative, but there is not the slightest evidence to indicate that the positive reactions are non-specific and there are absolutely no reasons for believing otherwise than that the longer persistence of the positive reactions under treatment is because the method possesses a greater

degree of sensitiveness as a detector of continued spirochetic infection of the tissues.

It cannot be too strongly emphasized, therefore, that the technic of the complement-fixation test bears a very important relation to this subject of the influence of treatment upon reactions.

It is true that with sensitive methods more treatment is required to bring about a state of permanently negative complement-fixation reactions with the serum and spinal fluid than with less sensitive methods and indeed, it may be impossible to bring about this result at all with so-called "Wassermann-fast" cases of syphilis, but if a technically correct positive complement-fixation test is acceptable as evidence of the continued presence of *Spirochæta pallida* in the tissues, even though some subjects may be clinically free of lesions and symptoms, we must face the issue and frankly confess our failure in bringing about a complete removal of the spirochetes from the tissues.

It is very easy indeed for both patient and physician to be lulled into a false sense of success in treatment by negative Wassermann reactions with insufficiently sensitive methods. In such instances, however, the serum is very likely at a later time to again yield positive reactions and much valuable time may have been lost in treatment.

It may be that time will teach us that cases of syphilis clinically free of symptoms but showing persistently positive Wassermann reactions with a sensitive test are indeed cured, but there is absolutely no reason at all at the present time for believing that such is the case; indeed, Warthin has shown that just the reverse is probably true and that in such cases spriochetes may still be present in the tissues, even though the serum and spinal fluid Wassermann tests yield negative reactions. While there may be a difference of opinion on the question of having too sensitive a complement-fixation test for the diagnosis of syphilis, I cannot understand how there can be a difference of opinion on the question of demanding as sensitive a test as possible for guiding the treatment of the disease and especially if negative reactions are accepted as criteria of cure. It is understood, of course, that I refer to technically acceptable tests yielding as sensitive reactions as consistent with specificity.

For this reason I have endeavored to render my new complement-fixation test as sensitive as possible with specificity. I have had absolutely no evidence at present that positive reactions are due to any disease in this country but syphilis. Experience has shown that treatment does bring about a gradual decrease in the degree of complement fixation and ultimately negative reactions, but the amount of treatment required to effect these results is greater than required to secure negative reactions with most other complement-fixation tests. We have long since given up the idea that one or even a few injections of arsphenamin is curative for syphilis, even though sufficient in some cases for dissipating the external lesions; let us frankly confess and realize that syphilis is not as easily and quickly cured as popular ideas and opinions profess, and that the majority of us are probably undertreating the disease.

Technic, therefore, greatly influences the value of the complement-fixation reaction as a guide in therapy and especially as a criterion of cure. Physicians cannot be sure of the cure of syphilis on clinical grounds alone, regardless of their experience and skill; one or more decades will be required to properly evaluate the results of present day methods of treatment. If the complement-fixation test is enlisted as an aid in guiding therapy and for determining cure, I repeat that the responsibility of both clinician and serologist is a great one and that much harm can be done by relying upon a defective method. Better, much better, to rely on clinical judgment alone

and treat syphilis by rule of thumb than to rely upon a short cut complement-fixation test yielding too many falsely negative reactions.

Finally, until we have a standardized technic, it is almost fruitless to attempt comparing the therapeutic results secured by one investigator with those of others, because the technic has such an important influence upon the reactions and results. One physician, for example, may report that four injections of arsphenamin cure 90 per cent. of cases of syphilis in the secondary stage as based upon the Wassermann reaction; another may find that this amount of treatment does not cure 10 per cent. of his cases, and both may speak of the "Wassermann test" when the tests employed by each my differ from each other in essential technical details—sensitiveness and specificity—as night from day, even though both are based upon Bordet's phenomenon of complement fixation. It is well for physicians to dismiss from mind that a Wassermann test is the same in all laboratories and it is imperative to have tests conducted with a technically correct method yielding as sensitive reactions as consistent with specificity, when employed for guiding the treatment of syphilis and as a criterion of cure.

Influence of Iodids upon the Complement-fixation Reaction in Syphilis. Potassium and sodium iodids administered orally in the usual amounts do not appear to have any constant effects upon the complement-fixation reaction in syphilis. It is difficult, however, to express a definite opinion, because so few cases of syphilis are treated exclusively with iodids. With rabbits experimentally infected with *Spirochæta pallida* and treated with sodium iodid by daily intravenous injection of 0.100 gm. per kilogram of weight (corresponds to 100 grains per 125 pounds) over a period of eight days after the sera had acquired an increased complement-fixing power due to syphilitic infection, no evidences of any effect of the iodid upon the lesions or complement-fixation reactions were elicited. Slight variations and fluctuations in complement-fixing power occurred as would be expected, but in no instance were negative reactions obtained.

In one case of latent syphilis yielding moderately positive complement-fixation reactions, potassium iodid was given in large doses over a period of several months in the treatment of a coincident actinomycosis; a series of complement-fixation reactions with my new method showed practically no effect upon the reactions. Eight months later, when the actinomycotic lesion had been healed, treatment of the syphilitic infection was undertaken with neoarsphenamin and mercury, with a gradual reduction in the strength of the complement-fixation reactions.

There is practically no literature upon this subject, but my tentative opinion based upon the above mentioned experiences is that the iodids alone probably do not materially influence the complement-fixation reaction in syphilis. Treatment of syphilis of human subjects with protiodid of mercury may exert an appreciable influence, but the effects are to be ascribed to mercury rather than to iodid.

Influence of Mercurial Compounds upon Complement-fixation in Syphilis.—It is readily understood that the influence of medication upon complement-fixation in syphilis will necessarily vary according to the rapidity and degree of therapeutic activity. For this reason mercury influences the serological reactions much more slowly than arsphenamin and allied products.

From 1907 to 1910 all reports on the influence of treatment upon the Wassermann reaction were based upon the use of mercury and the iodids, and the percentage of cases yielding negative reactions was comparatively small. The results, however, would have been even less noteworthy at this period if the technic of the Wassermann test had yielded more sensitive reactions. With more modern methods, the complement-fixation reaction

in syphilis is gradually brought to a negative state in some cases of syphilis treated with mercury, as indicated by the reports of Best,[16] Holler[17] and others; but with sensitive methods, the influence of intramuscular injections of the salicylate are weak and much inferior to arsphenamin and neoarsphenamin, as shown by the investigations of Nelson and Anderson[18] and Goodman.[19] Indeed, the latter investigators found that salicylate of mercury had so little influence upon the complement-fixation reaction in syphilis, that they have questioned the curative activity of this substance. Thus, Nelson and Anderson found that they did not obtain a single permanent negative reaction in 50 cases of syphilis treated by ten to twenty or more intramuscular injections of mercuric salicylate in dose of 1½ grains each given at intervals of one to two weeks. Goodman treated 87 previously untreated latent syphilitic patients with strongly positive Wassermann reactions with 1 grain of mercury salicylate intramuscularly at weekly intervals for courses of from six to eight injections. Tests made immediately after remained strongly positive in 66 per cent. of cases. In only nine was there a reversal to negative and later some of these yielded positive reactions.

Craig[20] has had an unusual experience in the army laboratories. All of 68 cases of syphilis, treated with mercury by mouth for periods ranging from nine months to three years, yielded positive complement reactions, whereas all of these later became Wassermann negative after eight weeks of salvarsan treatment. All of 18 additional cases treated with seven to thirty intramuscular injections of grey oil still gave positive reactions, whereas after salvarsan treatment all became Wassermann negative. Craig does not go so far as to state that the Wassermann test never becomes permanently negative after treatment with mercury, but it has been his experience that it is only in very rare instances that a permanently negative result is obtained from this drug alone, no matter how it is administered or in what dosage. However, he has also made the interesting observation that patients who have been previously well treated with mercury show a higher percentage of negative results after treatment with salvarsan than those who have received no mercurial treatment. Thus, of 75 patients who had received mercurial treatment before receiving salvarsan, 84 per cent. became negative, while of 110 patients who had received no treatment before the administration of salvarsan, only 74.5 per cent. became negative.

Somewhat better results have been reported by White, Hill, Moore and Young[21] with flumerin (disodium salt of hydroxymercurifluorescin) in the treatment of primary and secondary syphilis. In dose of 0.003 gm. per kilogram corresponding to about 0.2 to 0.3 gm. for an average adult, by intravenous injection, flumerin was therapeutically active in the sense that it caused spirochetes to disappear from lesions, brought about the resolution of lesions, and, in about half the cases treated, changed a positive blood Wassermann reaction to negative. In a group of tertiary cases a reduction in the degree of complement fixation, but not always to the negative, was obtained in 9 of 25 cases, while in 16 the reactions remained positive.

My own experience with the new complement-fixation test has been largely confined to the treatment of syphilis with inunctions of mercury and it corresponds very closely with that of Craig, Nelson and Anderson and Goodman referred to above. In other words, cases of chronic syphilis treated over periods ranging from four to ten weeks with daily inunctions have shown only a slight influence upon the complement-fixation reaction, but in no instance reversed the reaction from positive to negative. However, I have reason to believe that periodical courses of mercury by inunction have served to aid in maintaining a state of negative reactions over periods of one to two years; that is to say, have probably eradicated the last vestiges of *Spirochæta pallida* infection or at least have held the infection in check, and thereby prevented sufficient activity of the infection to prevent a reversal of the complement-fixation reactions from negative to positive.

Undoubtedly mercury exerts a therapeutic action in syphilis but mercury influences the complement-fixation reaction much more slowly and effectively than arsphenamin, although a combination of the two yields better results in the treatment of chronic syphilis than either alone.

Influence of Arsphenamin, Neoarsphenamin and Allied Compounds upon Complement Fixation in Syphilis.—Arsphenamin and its allied compounds, as neoarsphenamin and silver arsphenamin, influence complement-fixation reactions in syphilis more profoundly than any other medicaments. Ordinary arsenical compounds, as sodium arsenate, sodium arsenite and

sodium cacodylate, have no influence at all; and pentavalent compounds, like atoxyl, tryparsamid, etc., vary considerably in this regard, as will be discussed shortly in more detail.

As so clearly shown by Detweiler,[22] the influence of these compounds upon complement-fixation in syphilis is best brought out in tests employing varying amounts of serum. The same has been found true with my new test by Schamberg and Klauder,[23] Shivers,[24] Palmer and Gibbs,[25] Kilduffe,[26] Schamberg and Greenbaum[27] and others. These clinicians and serologists have found that, even though the test is very sensitive, negative reactions do occur under treatment, and my own experience has yielded exactly similar results.

In *primary syphilis* the reactions are usually weakly to moderately positive in my new test after the tenth day of the sore. As shown in Chart 1, the reactions are usually reduced to negative after about five doses of neoarsphenamin at intervals of three to four days. Cases of longer duration, with stronger positive reactions before treatment is begun, require more injections and no two cases are ever exactly alike. Sometimes, as shown in Chart 2, a weakly positive reaction is followed by stronger reactions and

these in turn by a gradual or sudden reduction to the negative state. I have interpreted such reactions as an indication of ascending spirochetic infection, in spite of one or two doses of neoarsphenamin, followed by destruction of the parasites.

The two charts were plotted according to the smallest doses of serum yielding positive reactions, the method of recording the reactions having been already described in the preceeding chapter. Hardly any two cases ever react just alike, but these charts are fair examples of the average results. It is peculiar how suddenly the reactions will sometimes drop from strongly positive to negative, or jump from negative to positive and back again with the smaller doses of serum. At any rate, practically all cases of syphilis in the primary stage yielding positive reactions can be rendered negative and kept in this state by appropriate treatment with arsphenamin or neoarsphenamin.

Similar results are usually observed in the treatment of *secondary syphilis*. Arsphenamin, however, in dose of 0.6 gm. intravenously usually reverses the complement-fixation reaction from positive to negative more rapidly than neoarsphenamin. As a general rule, positive complement-fixation reactions in cases of secondary syphilis treated with arsphenamin and neoarsphenamin are gradually reversed to negative; but the reduction may not be progressive or orderly, but interrupted by sudden and inexplainable increases of complement-fixation followed by sudden decreases.

In *chronic syphilis*, however, the influence of treatment upon reactions with my new complement-fixation test are much more irregular. In both latent and active cases far more treatment with arsphenamin, neoarsphenamin or sulpharsphenamin is required for reversing the reactions than with the old test which was a modification of Wassermann's method employing three antigens.

No two cases ever appear to react exactly like and practically never in my experience is the reversal from positive to negative orderly and progressive. In chronic latent syphilis especially, the degree of complement fixation is up and down, as shown in Charts 3 and 4, and single negative reactions are of no significance whatsoever. Indeed, a series of two or three consecutive negative reactions in a short space of time is of little significance although negative reactions over a period of one or two years are of much more significance as a criterion of cure.

In both latent and active cases of chronic syphilis, and especially in the former, the complement-fixation reactions are apt to become stronger after one or more injections of arsphenamin or neoarsphenamin, and these effects are attributable, in part at least, to a provocative influence of the drugs upon the parasites. In late congenital syphilis the reactions are particularly difficult to influence and may require two or more years of persistent treatment with neoarsphenamin, mercury and potassium iodid to finally reverse the reactions. In chronic active syphilis, I believe that it is usually easier to

reverse the complement-fixation reactions, with proper medication, that in chronic latent acquired or congenital syphilis.

Silver arsphenamin is regarded by some physicians as somewhat more spirocheticidal than arsphenamin and that positive complement-fixation reactions are reversed to negative more rapidly than with arsphenamin or

neoarsphenamin. I have never used the compound extensively in the treatment of human syphilis and am unable to express an opinion of its influence upon the complement-fixation reaction, although my limited experience has indicated that its effects are about the same as observed with neoarsphenamin.

Sulpharsphenamin likewise influences the complement-fixation reaction, but at this writing I am unable to express a definite opinion as the compound has not yet been employed for a sufficiently long period of time in my practice in the treatment of human syphilis; in a preliminary manner I may state however, that the effects upon my complement fixation reaction have been much less than with arsphenamin and slightly less than in treatment with neoarsphenamin.

Influence of Sodium Cacodylate, Tryparsamid, and Other Arsenical Compounds upon Complement Fixation in Syphilis.—*Sodium cacodylate*, which at one time was regarded as almost equal to arsphenamin in the treatment of syphilis, has practically no influence upon the Wassermann test; as discussed in Chapter XXIII, it is now proven that it has but very slight spirocheticidal activity and is not now generally employed for the treatment of syphilis.

Striking results, however, have been reported by Lorenz, Loevenhart, Bleckwenn and Hodges[28] in the treatment of neurosyphilis with *tryparsamid* alone and in conjunction with mercuric salicylate. The former was injected intravenously in dose of 3 gm. once a week for eight weeks; the salicylate was injected intramuscularly in dose of 1 grain once a week (three days before tryparsamid) for a total of nine injections. After a rest of five to eight weeks this course was repeated, and after another rest was repeated a third time, if the case showed continued activity or was serologically positive. Of 68 cases of paresis, negative reactions were obtained with the sera of 84 per cent. and with the spinal fluids of 30 to 42 per cent. Of 5 cases of taboparesis, negative serum reactions were obtained with 67 to 100 per cent. and negative spinal reactions with 33 to 50 per cent. Of 5 cases of tabes, negative serum reactions were secured with 100 per cent. and negative spinal fluid reactions with 25 to 100 per cent. Of 9 cases of miningovascular syphilis, negative serum reactions were obtained with 75 to 100 per cent. and negative spinal fluid reactions with 37 to 50 per cent. Of 9 cases of generalized syphilis, negative serum reactions were obtained with 42 to 100 per cent. These are truly wonderful results and, if confirmed, will firmly establish the combined treatment of neurosyphilis with tryparsamid and mercury and prove a valuable advance in the treatment of syphilis of the central nervous system.

According to Wright, Kennell and Jussey,[29] *disodium ethyl arsonate* (mon arsone) has an effect upon the Wassermann reaction in syphilis, but as discussed in previous chapters this substance has slight or no trypanocidal and spirocheticidal effects in experimental infections and is not now employed in the treatment of syphilis. Like sodium cacodylate, this compound probably does influence the symptoms of syphilis, but probably more by promoting the absorption of syphilitic exudates than by direct spirocheticidal effects.

Influence of Bismuth upon Complement Fixation in Syphilis.—A review of the literature on the effects of various salts of bismuth, and especially the quadruple salt of potassium and sodium tartrobismuthate, upon the complement-fixation reaction in syphilis, indicates that in this respect bismuth is more active than mercury and less active than arsphenamin and neoarsphenamin. As a general rule, the various bismuth preparations have been injected intramuscularly either in solution or in oily suspension.

Sazerac and Levaditi,[30] who first employed bismuth for the treatment of human syphilis, found that in the primary and secondary stages positive complement-fixation reactions were reversed to negative; likewise, in tertiary syphilis, but very slowly. In more extensive studies by Fournier and Guenot,[31] positive reactions in 35 cases of primary syphilis were reversed to negative in 16; in secondary syphilis none became negative with the first course of treatment, but the majority were reversed to negative with the first course of treatment, but the majority were reversed to negative by a second course. They arrived at no con-

clusions regarding the effects of bismuth upon the Wassermann reaction in tertiary syphilis. Pardo-Castello[32] reports that, of 9 cases of syphilis treated with quinin bismuth iodid, the Wassermann reactions were reversed from positive to negative in 7. Klauder[33] found that sodium and potassium tartrobismuthate in watery solution and in oily suspension, potassium tartrobismuthate in watery solution and bismuth trioxid in olive oil had a favorable influence upon reactions conducted with my new complement-fixation test. The majority of cases of secondary syphilis with strongly positive reactions reacted negatively after the total administration of about 2 gm., while a few required 3 gm. or more before negative reactions were secured. Similar results were observed in cases of primary syphilis. In cases of tertiary syphilis presenting strongly positive reactions, a reversal to negative was observed in some after treatment with each of the three preparations employed. In two cases of early syphilis, however, the sera later yielded positive reactions.

Hopkins[34] reports that a case of primary syphilis with a strongly positive complement-fixation reaction was reversed to negative by six intramuscular injections of potassium and sodium tartrobismuthate in dose of 0.1 to 0.2 gm. at intervals of a week. Similar results were observed in three cases of secondary syphilis. Of 43 cases of latent syphilis with positive Wassermann reactions, 31 of whom had had previous treatment with arsphenamin, mercuric salicylate or both, only one with a strongly positive reaction was reversed to negative by sixteen to twenty-three injections of bismuth and only four with weakly positive reactions were reversed to negative by four to twenty-two injections. A number of patients gave a weakened reaction after their first series of bismuth injections and then had a relapse in spite of subsequent treatment. There were, however, several cases in which considerable treatment with arsphenamin and mercury had exerted no apparent influence, but which showed the first break in their series of strongly positive reactions after taking bismuth. There were also one or two that had relapsed to a weak positive after previous treatment who seemed more definitely influenced by bismuth, and Hopkins surmizes that bismuth may prove useful in the treatment of some of these resistant cases.

Cajal and Spieser[35] have reported that in congenital syphilis the complement-fixation reactions are reversed to negative along with prompt cicatrization of lesions. McCafferty[36] reported that, in 5 cases of primary syphilis, 2 of which gave a positive Wassermann test, the intramuscular injection of 0.2 gm. of potassium and sodium tartro-bismuthate in oil suspension every four days for twelve to sixteen doses resulted in a disappearance of spirochetes in all and negative complement-fixation reactions in 4. In 3 cases of secondary syphilis with strongly positive reactions, two courses of sixteen injections each reversed the reactions to negative. Of 17 cases of tertiary syphilis, 16 of which presented strongly positive reactions, reversal to negative was observed in 3 after one course of twelve injections and in 4 after two courses; in 9 patients receiving one to two courses of injections the complement-fixation reactions were weakened in some but were not reversed to negative.

Practical Value of the Complement-fixation Reaction as a Guide in the Treatment of Syphilis—Lack of Conformity between Symptomatic and Serological Effects.—From the preceding review it is apparent that in a general manner the compounds commonly employed in the treatment of syphilis influence the complement-fixation reaction of the serum in the same ratio as their respective spirocheticidal activities. Arsphenamin is undoubtedly more spirocheticidal than neoarsphenamin and likewise reverses the serological reactions somewhat more promptly; arsphenamin, neoarsphenamin and allied compounds are in turn as a group more spirocheticidal than bismuth, and bismuth more than mercury, and mercury more than potassium iodid, and these relative curative properties are reflected in the same order upon reversal of positive to negative complement-fixation reactions.

It is true that with more sensitive complement-fixation methods the rapidity of reversal is not as prompt and spectacular as in former years when less sensitive methods were employed, but our ideas of the rapidity of cure by arsphenamin and allied compounds have likewise undergone considerable change from clinical developments alone. However, it is common experience to find symptomatic improvement before serological improvement; in other words, courses of treatment sufficient for dissipating the obvious lesions of syphilis may not greatly influence the complement-fixation reactions. Mainly for this reason Kaplan,[37] Wile and Halsey,[38] Oettinger[39] and others do not regard the complement-fixation test as of much practical value in the treatment of syphilis. As previously stated, only another decade or two will

teach us conclusively who is right in this matter. We must watch and determine in the future what proportion of cases develop relapses when treatment is stopped only after securing persistently negative complement-fixation reactions, as compared with those dismissed free of obvious lesions at the time but still serologically positive. My prediction is that the latter group will show a much higher percentage of relapses and I believe it is a serious error to disregard a technically acceptable positive complement-fixation reaction as evidence of existing spirochetic infection, even though the patient has had considerable treatment and is to all intents and purposes recovered clinically as far as this is to be ascertained at the time. All evidence at present indicates that a persistently positive reaction is an indication of continued infection; time may show that is an error, but I do not believe or expect this outcome.
